INTRODUCTION

WHAT are these calories? Can they be taken in tablet form, or do we have to mix them with our food? Neither! Calories are heat units. They come already mixed with the food. They constitute its *energy* content. We cannot live without them. Although too many of them may not be good for those who wish to remain slender, or even for those who wish to remain healthy, a sufficient number of them we must have, for without them we die. Every animal, every plant, everything that lives is looking for calories. But not only the living world, the non-living must also have its quota. Everything that happens is due to the flow and transformation of energy. Without its calories in the right places, and in the right numbers, the universe itself dies.

The gods did well to bind Prometheus to the rocks when he stole fire from heaven, for by this act he enabled men themselves to become like gods and to rule the elements. Control fire, and you control everything. The discovery of fire was indeed the greatest achievement of primitive man, the one thing that more than any other lifted him from the level of the beast, and gave him dominion over the earth. Heat is his most powerful and obedient servant. It cooks his food, warms his dwelling, moves his machinery, and performs a myriad of useful services for him.

Heat has a profound effect upon the states and conditions of matter. Every property of matter is altered by a change in temperature—the density, pressure, hardness, strength, electrical conductivity, in short everything that one can mention. Whatever happens in this physical world of ours, one has always to reckon with the temperature or the quantity of heat involved.

Some of these effects of heat, and some of its ways that can be helpful to man, are described in the following pages.

Acknowledgments are due to Mr. James T. Barkelew, who painstakingly read the manuscript of this book, corrected some errors, and made many valuable suggestions; and to Mr. Carl Nagashima, whose skillful pen lettered the diagrams.

HEAT
AND
ITS
WORKINGS

I

THE TEMPERATURE
SENSE

THERE is a very old and simple experiment described by John
Locke in 1690 in his *Essay Concerning Human Understanding*, and
it was doubtless old even then.

Let the two hands be immersed, one in a basin of hot water,
the other in a basin of cold water. Then after a time plunge
both hands into a bath of intermediate temperature. The
water will seem cold to the one hand and hot to the other.
What is the explanation? Says Locke:[1] "If the sensation of
heat and cold be nothing but the increase or diminution of the
motion of the minute parts of our bodies, caused by the cor-
puscles of any other body, it is easy to be understood, that if
that motion be greater in one hand than in the other, if a body
be applied to the two hands, which has in its minute particles a
greater motion than in those of one of the hands, and a less than
in those of the other, it will increase the motion of the one hand
and lessen it in the other, and so cause the different sensations
of heat and cold that depend thereon."

Even at that early date Locke conceived of heat as a motion
of the minutest particles of bodies. In this he was much ahead
of his times, for this view was not definitely adopted by science
until a hundred and fifty years later. Yet his explanation could
not have been more perfect had it been written yesterday.

According to this theory then, a body seems hot when heat is
conveyed to the hand, and cold when heat is conveyed away
from the hand. The temperature of the human body thus
forms the dividing line between what we call hot, and what we
call cold, and the position of this line is variable. The distinc-
tion cannot therefore be an objective one. Outside of our

[1] Book II, Chapter VIII, § 21.

subjective impressions, there are no cold bodies.   All bodies are
hot, and their degrees of hotness are measured up from some
absolute zero of complete heat absence, which lies far below the
temperature of the human body.

Another old experiment is this: If we touch successively
hotter and hotter bodies, the sensation of heat increases for a
time, but soon becomes painful.   When the bodies are very
hot, we cannot distinguish their temperature differences at all,
but receive only the stinging sensation of a burn.   Similarly if
we touch successively colder bodies, the sensation of cold
increases up to a certain point, and then becomes painful.   An
extremely cold body produces a burn just like a hot one, and to
the touch is indistinguishable from it.   This fact was mentioned
by Francis Bacon in his *Novum Organum* in 1620.

In sensation, then, there is a maximum of hotness and a
maximum of coldness.   We speak of things being boiling hot
or ice cold, as though nothing could be hotter or colder.   That
FIG. 1— WEBER'S LAW FOR SENSATION

these expressions were not always mere figures of speech was
made evident to the writer by a little experience he had while a
student in Germany.   He was discussing high temperatures
with a friend, and the landlady of his boarding house happened
to be listening in.   As the temperatures rose higher and higher,
she grew more and more restive until at last, when it was men-
tioned that the melting point of platinum was 1700 degrees
centigrade, she burst out with "Ugh!   There aren't so many
degrees."   "How many do you think there are?" we asked.
"At most, two hundred," she replied.   Doubtless even at that
she was stretching a point, for water boils on the centigrade
scale at 100 degrees.

Modern psychologists have reduced the relation between
sensation and stimulus to mathematical law.   They find that,

as the stimulus is successively doubled, the sensation increases only additively. This is known as Weber's law. If we plot the stimuli horizontally, and the corresponding sensations vertically, we obtain the curve of Figure 1. The power of discrimination at any point is represented by the steepness of the curve, for when the curve is steep, it means that a small increase in stimulus will produce a large increase in sensation, and will therefore be the more perceptible. Now the curve is steepest at the beginning, and becomes less and less steep as we ascend. Hence the power of discrimination is greatest for the smallest stimulus, and diminishes as the stimulus increases. Note also that the curve does not start quite at the left-hand corner of the diagram, but a little to the right of this point. That means that the stimulus must reach a certain value before any sensation is felt at all. This value is called the *threshold*. Our sensations are therefore by no means proportional to the stimuli that produce them. They have limited and variable discrimination, and a limited range.

Our temperature sense being thus unreliable, and at times even contradictory, we naturally turn to something else, to some instrument that shall be exempt from human weaknesses. But every instrument that we can devise possesses these same defects, though in less degree. For example, if a mercury thermometer is first highly heated and then greatly cooled before being plunged into a bath of intermediate temperature, it will not on the two occasions register the same temperature. Beyond the boiling and freezing points of mercury, the instrument will not register any further temperatures at all. It has a limited range. A certain difference in temperature must exist before the instrument will respond. It has a threshold. It has limited discrimination or sensitivity. Finally, who can say if its readings are proportional to the temperature, and if not, what law they follow? What *are* true temperatures, and how are we to know them if our senses fail and every instrument is doubtful? That is a big problem.

Once while the author was staying at a primitive village, he sent for a nurse of the village to attend one of his children who was ill. The nurse put her hand on the child's forehead to see if there was fever. The author proffered a clinical thermometer. It was spurned. The nurse said she could tell how hot a patient was "without no thermomiker." Who, indeed,

could tell if the "thermomiker" were right? We rely upon the maker. But how does he know? We take it to a laboratory to have it tested, and there it is compared with a big thermometer, which we are told is "standard." But how does the physicist know that his "standard" is right? Perhaps he admits it is a little bit wrong. But then, he has a table of corrections. Where did that come from? Very likely he will tell us that he made it himself. Did he then compare his thermometer with some other still more "standard"? No, he never went out of his laboratory. He only examined his own instrument and made out his own corrections. At this point we hand him a dollar bill for his services, and remark: "We know this bill is good because we made it ourselves."

Now how did the physicist know that his thermometer was a little bit wrong? Certainly he didn't feel of it like the nursemaid to see how hot it was? Yet what does he know about temperature, other than what his senses reveal or some instrument indicates? How does any one know what a temperature is, better than a thermometer? How can any one tell what the thermometer ought to read when it doesn't read what it ought to?

The answer is that we make assumptions. They are not made up out of whole cloth to be sure; they are *reasonable* assumptions; they are *guided* by experience as far as that is possible; but, nevertheless, they go *beyond* experience. Science always does this, and, indeed, could not get very far if she didn't.

Bodies expand when heated. The gross fact can be ascertained with no better temperature indicators than our fingers. Suppose, for example, we dip a tube of small bore, with a bulb blown on one end and filled with mercury, into a water bath that is decidedly cold to the touch. We make a scratch on the tube at the level where the mercury stands. Now we transfer the tube to a bath that is decidedly hot to the touch, and note that the mercury stands at a higher level. It has expanded. Let us mark the new level. Now suppose that we measure the distance between the two marks with any convenient scale, say, a millimeter scale, and find that the distance is fifty millimeters. Never mind how large a millimeter is. It doesn't matter in the least. Now let us dip our instrument into two other baths, and suppose that in one of them the mercury

stands one millimeter higher than in the other. We *see* that the mercury has expanded, but we *perceive no difference in temperature*. We very naturally assume that there *is* a difference in temperature even though we cannot feel it, and say that it is below the power of discrimination of our senses. This is a very *reasonable* assumption, but it is an assumption none the less. If it is a fact, then we have already in this crude instrument a means of sharpening the senses. It can indicate temperature differences which are less than we can perceive. Or, rather, we have translated our rather dull tactile sensations into the much sharper visual ones.

Shall we make a further assumption? Shall we assume that the rise in temperature that produced an expansion of one millimeter is just one-fiftieth of the rise in temperature that produced an expansion of fifty millimeters? In short, shall we assume that the expansion of mercury is in exact proportion to the rise in temperature? That would be extremely convenient if true, for it would enable us accurately to measure and compare different temperature changes. But how can we test the assumption if our senses are too dull, and we have as yet no instruments? We cannot test it directly; but indirectly we can get a rough idea of how much it may be in error, and if the probable error is not too great, the assumption may be adopted as a good enough approximation, at least until a better can be found. This, in fact, is what we do.

Let us examine the expansions of other liquids, water itself, alcohol, etc., in exactly the same way we did that of mercury. We make a little tube for each, put them all in the same cold bath, then in the same hot bath, and mark the positions of the liquids in each case. We now put them all in a bath for which the mercury height stands at twenty-five millimeters. Will all the others stand at exactly their halfway marks? Very nearly, but not quite. In the same way we may test the quarter, the three-quarter, and other marks, and shall again find near agreements. We may therefore conclude that, while perhaps none of these liquids expands in exact proportion to the temperature, none departs far from it. The assumption of proportionality cannot be far from the truth.

And so this convenient assumption is made, and thermometers are constructed in much the way we have described. Even with the crude instrument we have discussed, one can

discover, and, indeed, it was early discovered with instruments
but little less crude, that ice always melts at the same tem-
perature, and that water under a pressure of one atmosphere
always boils at the same temperature.   So the thermometer
maker plunges his yet ungraduated instrument into a mixture of
melting ice and water, and marks on the stem the point at which
the mercury stands.   He then suspends it in the steam just over
boiling water and marks the point to which the mercury then
rises.   The difference in temperature between the freezing and
the boiling points of water thus provides a natural temperature
interval, which is always the same, and always reproducible.
This standard interval, as marked on his thermometer, can
now be subdivided in any convenient way.   If he is making a
centigrade thermometer, he will mark the lower point, o degree,
and the upper one 100 degrees.   Then he will place the ther-
mometer in a dividing engine and accurately divide the distance
between these two marks into one hundred *equal* parts.   If the
thermometer is to register above or below these marks, he will
add further divisions of the *same size* above or below them.   If he
is making a Fahrenheit thermometer, he will label the freezing
point 32 degrees, and the boiling point 212 degrees, and divide
the distance between into one hundred and eighty equal parts,
continuing the same graduations above and below if required.

It should be noted that by this mode of construction a further
assumption is made, namely, that the expansion of mercury
in a glass tube is strictly proportional to the rise in temperature.
The glass expands as well as the mercury, only less so, and what
the instrument really shows is the difference between these two
expansions.   If different kinds of glass do not expand equally,
then thermometers made of different kinds of glass will show
variations.   In fact they do; but the variations are very slight.
From the manner of their construction, it is evident that all
these thermometers will agree at the ice and steam points.
The disagreements will occur elsewhere on the scale.

If a substance other than mercury is used in a thermometer,
the procedure is exactly the same, as though the expansion of
this substance in a glass tube were also uniform.   Each sub-
stance is said to give a particular *thermometric scale,* and these
differ somewhat among themselves.   From among them we
select the *mercury in glass scale,* and *decree* that it shall be right.
We do this, not because we know that it is right and the others

wrong—they are probably all wrong —but because for many reasons mercury is the most convenient substance to use. Hence the mercury thermometer is right, not because it shows true temperatures, but because we have virtually defined temperature to be what such a thermometer shows. It is like the Professor's wonderful watch, described by Lewis Carroll in his story of *Sylvie and Bruno*. The watch was always right, not because it went according to the time, but because time went according to the watch. If you turned the hands forward, you jumped into the future. If you turned them back, you slipped into the past. And if you pulled out the wonderful reversing peg, everything went backwards. It certainly would be surprising to see everything going backwards, as Lewis Carroll and so many others have described it; to see, for example, the droplets of water sprinkled all over the lawn gather themselves together and shoot back into the hose nozzle. But we would not see it. The rays of light that had entered the eye and rendered objects visible, would now leave the eye and return to the objects. All the light in the world would gather itself up and return to the sun. The stars would likewise pull in their rays and leave the universe in utter darkness.

And how does the physicist correct his thermometer? He simply makes an investigation to determine whether it has been properly constructed and marked. He puts it again in the melting ice and water, and again in the steam over boiling water, and sees if these points have been correctly marked. If not, he notes the errors and calculates the resulting corrections for each point of the scale. Then he tests whether the bore of the tube is uniform. If not, he again makes corrections for each point of the scale for the variations he finds. Then he sums up all his corrections and makes a table. It is very simple. He does not have to go out of his laboratory. He can even make his own thermometer, and if done properly according to the rules, it will be right.

When a liquid is used as a thermometric substance, the instrument is necessarily limited to the range of temperatures between the freezing and boiling points of the liquid. Indeed, only a part of this range can be used, for as either limit is approached, the expansion becomes markedly irregular, as shown by comparison with thermometers using other substances. Of all liquids, however, mercury is the best in this regard, for it

freezes at −38 degrees and boils at 674 degrees Fahrenheit, having thus a maximum range of 712 degrees, a good part of which can be used.

A gas can also be used as a thermometric substance, and has the advantage of a much greater range of temperature. Air, for example, liquefies at −300 degrees Fahrenheit, while the upper limit of such a thermometer is set only by the melting or softening point of the material of which the bulb is made. The scale is determined in the same way as with liquids. The volume or the pressure of the gas is measured at the freezing and boiling points of water, and the interval between is divided into one hundred or one hundred and eighty equal divisions. The temperature is then read off on this scale in the usual way. The various gas scales were found to agree among themselves better than the liquid scales did. Hence, they were deemed better scales, and the hydrogen or nitrogen scales were made standard in place of the mercury.

Thus we came to have several thermometric scales, all of them based on doubtful assumptions, probably none of them exactly true, but some apparently better than others. No one knew as yet what temperature was in a physical objective sense, nor how it could be determined other than by its *effect* on some material substance. And whether that effect were strictly proportional or not, there was no means of ascertaining.

The establishment of the mechanical theory of heat, in 1845, at last made possible a physical conception of temperature. According to this theory the temperature of a body is proportional to the average kinetic energy of its moving molecules. But no one knew at first how to translate this idea into thermometer degrees. The task was finally accomplished by William Thomson (Lord Kelvin) in 1852. He then established what he called the *thermodynamic* scale of temperature. The degrees of this scale, being determined solely by *mechanical* units, are independent of the effects of temperature upon any material substance. In fact, by means of it we can determine how far these effects deviate from true proportionality. Thus, Thomson and his coworker, Tait, drew up tables of corrections for the other scales, by which they could all be reduced to the thermodynamic. The corrections amounted only to hundredths of a degree for the hydrogen scale and to tenths for the mercury, over the ranges for which these scales are ordinarily

used. Hence they turned out to be rather better than what might have been expected from the way they were made. For nearly all purposes, even scientific ones, they are still quite good enough. And liquid and gas thermometers are still made in the way described above, corrections being applied only for the most accurate work. For everyday use, temperature still is, what for most people it has always been, simply what the mercury thermometer says.

II
THE EXPANSION
OF BODIES

THAT bodies in general expand when heated and contract when cooled is well known. Probably every one has at some time removed a glass stopper that had become wedged in the neck of a bottle, by heating the neck, or has performed some similar operation, in which advantage is taken of thermal expansion. If one tightly corks a thermos bottle immediately after the latter has been filled with a hot liquid, he is apt to find after several hours, when the liquid has cooled and contracted, that the cork has been drawn in so tightly that it is very difficult to remove. On the other hand, if he puts the cork in lightly when the bottle is filled with a cold liquid, he will find after some time, that the expansion of the contents has loosened the cork, and, if the bottle has lain on its side, the contents may have spilled. Hence, when the liquid is hot, the cork should be put in lightly; and when it is cold, the cork should be put in tightly.

The expansion of a gas when heated is far greater than that of any other body, and was the first to be observed. Hero of Alexandria in the first century A.D. heated a flask full of air, then sealed it and allowed it to cool. When the seal was broken, air was sucked in. By first inverting the cooled flask and dipping its neck under water, when the seal was then broken, water was sucked in. In this way Hero was able to measure the contraction; but he had no way of determining the temperatures. We now know that when air is heated from the freezing to the boiling point of water, its volume increases by about one third. All gases show similarly large expansions.

Hero applied the expansion of air to the production of various mechanical wonders and temple tricks. His most noted achievement of the sort was to cause the doors of a temple to

open mysteriously when a fire was built upon the altar. His apparatus, concealed beneath the pavement, is shown in Figure 2. The altar was hollow, and when a fire was built upon it, the air in this space expanded and passed down into a flask below, that was partly filled with water. Some of the water was thus forced out through a bent tube into a suspended bucket, which, thus weighted, pulled open the doors of the temple in the manner shown. When the fire was extinguished, the air in the flask cooled and contracted, and the water was sucked back into it. The bucket being thus lightened, the doors were pulled shut by a counterweight attached to the ropes that disappear in the drawing under the floor of the temple.
FIG. 2— HERO'S TEMPLE TRICK

Galileo Galilei appears to have been among the first to suggest that the expansion of a body could be used to indicate changes in temperature, and that air, on account of its considerable expansion, was very suitable for this purpose. In 1592 he made the world's first thermometer. It was an air thermometer. His simple device is shown in Figure 3. It consisted of a bulb having a long narrow stem projecting downward into a dish of mercury. Before dipping the stem into the mercury, the air in the bulb was slightly heated, so that, on

cooling, mercury was drawn part way up the stem. There-
after, variations in the surrounding temperature produced
variations in the height of the mercury column. In this upside
down thermometer, what we call *low* temperatures thus read
high, and high ones low; so that, had this form of instrument
persisted, our ideas of high and low as applied to temperatures
might have been reversed.

In this instrument, the air, of course, not the mercury, was
the thermometric substance. The mercury served merely as
an index to show changes in the volume of the air in the bulb.
On account of the open dish, changes in the volume of the
mercury produced little effect. The readings were affected,

FIG. 3 —GALILEO'S AIR THERMOMETER

however, by changes of atmospheric pressure, so that readings
taken on different days were not comparable. But the exist-
ence of this pressure and its variations were not then known.
The barometer was yet to be invented by Galileo's pupil
Torricelli.

This thermometer had no graduations. The mercury height
was simply measured by applying a scale. Hence the instru-
ment could scarcely have had any other use than to detect
changes in temperature smaller than the senses could perceive.

Otto von Guericke, the inventor of the air pump, constructed
a huge thermometer of this type. Figure 4 is reproduced from
his *Experimenta Magdeburgica*, written in 1672. The great globe
at the top was the thermometer bulb filled with air. Instead of

mercury, alcohol was used as an index substance, and was contained in a U-tube, as shown in the left-hand view of the instrument from which the scale cover has been removed. A little float rode on the surface of the liquid in the open arm of the U-tube, the other arm of which connected with the air bulb.

FIG. 4   OTTO VON GUERICKE'S THERMOMETER

From the float a cord passed up over a pulley, and at the other end was suspended a little angel, by whose movements up and down the changes in temperature were indicated. This thermometer had a scale of a sort, as the right-hand view shows. The divisions, rather large, were not numbered, but were provided with various names, ranging from "greatest heat" to "greatest cold." Von Guericke's directions for setting the scale are interesting. One was to select an evening in the autumn just before the harvest, when the temperature was medium, and then draw air out of the globe, by means of a stopcock provided for that purpose, until the angel hung at the middle of the scale which is marked "temperate heat." Some of our household

thermometers to-day are still marked with temperate heat, summer heat, blood heat, etc., in addition to the numbered scale, for the benefit, perhaps, of those whose thermometry has not advanced much beyond that of von Guericke.

One may ask what the use of this huge instrument could be, which only told whether it was very hot, or moderately hot, etc., in the judgment of whoever set the scale. Von Guericke tells us enthusiastically. By means of it, he says, one can keep track of the temperature of every day in the year, and actually tell which was the hottest and which was the coldest day. One can tell whether this winter is colder or warmer than last winter, and in the course of time, I suppose, could decide the perennial question as to whether our present winters are not what they used to be twenty years ago. That would indeed be useful. But all the resources of the weather bureau seem unable to accomplish it even to-day.

Galileo observed, also, the expansion of liquids, which is much less than that of gases. Alcohol expands one-third as much as air; water, at 70 degrees Fahrenheit, one twenty-fifth as much as air. The others fall in between. Galileo also suggested the expansion of alcohol as a temperature indicator, and around 1640 spirit thermometers much like our present instruments began to appear. The most widely used instrument of this type was the famous "Florentine Thermometer," illustrated in Figure 5. In making it, the bulb was filled with alcohol and heated until the stem was completely filled. The top was then sealed off. On cooling, the liquid descended, leaving a vacuum above it, except for the vapor of the liquid. Being thus hermetically sealed, these instruments were not affected by changes in the atmospheric pressure. Being small and light, they were transportable, and could be inserted into small places or into liquids whose temperature it was desired to measure. The divisions were marked by enamel beads fused onto the stem, and represented thousandths of the volume of the bulb. The user was thus left to interpret for himself the meaning of the readings as regards temperature. These instruments continued in use for about a century.

FIG. 5—A
FLORENTINE
THERMOMETER

One disadvantage of alcohol as a thermometric substance is that it wets the tube. Consequently, when such an instrument is quickly cooled, the liquid adhering to the walls continues to drain down for some time. In 1693 Halley suggested that mercury be used, and such thermometers were soon made. Although the expansion of mercury is about one-sixth that of alcohol, the fact that it does not wet the glass makes possible the use of much smaller tubes, and this offsets the lesser expansion. The finer the bore, and the larger the bulb, the more sensitive the thermometer. A given change in volume of the mercury will then produce a greater change in the length of the mercury thread.

All the early thermometers suffered from the defect that they had no common easily reproducible scale. Different thermometers read the same temperature differently, just as different radio dials to-day read the same wave length differently. All comparisons of temperature had to be made with the same instrument. Nevertheless, with these thermometers some important discoveries were made—among others, that liquids have fixed boiling and freezing points, so that the readings of different thermometers could be compared by observing where these boiling and freezing points occurred on their scales. In 1665 Boyle suggested that all temperatures be measured up from the freezing point of water. In 1693 Halley suggested they be measured down from the boiling point. Either of these suggestions, however, still leaves the *size of the degree* undetermined. In order to establish a common unit of temperature *difference* that will be independent of the make of thermometer, it is necessary to select *two* naturally fixed points, and make the unvarying interval between them the yardstick of temperature measurement. The interval can then be subdivided in any convenient fashion.

The first to embody this principle in the construction of a thermometer was Fahrenheit in 1724. He used for his lower fixed point a mixture of water, ice, and sal ammoniac, which gave the lowest then-known artificial temperature. This he took as the zero of his scale. For the upper fixed temperature, he used the boiling point of water, which he called 212 degrees. The distance between the two marks on his thermometer stem, he divided into 212 equal parts, thus producing the prototype of the instrument so much used to-day.

It was soon found, however, that the sal ammoniac mixture did not give a reliably fixed temperature. In 1730 de Réaumur substituted the freezing point of water for the lower fixed temperature, and retaining the boiling point for the upper one marked them o degree and 80 degrees, respectively, with eighty equal divisions between. This scale is still much used in Continental Europe. In 1742 Celsius devised a scale in which

FIG. 6—COMPARISON OF THERMOMETER SCALES

he used the same fixed points, but labeled them o degree and 100 degrees, respectively, with one hundred equal divisions between. This is the centigrade scale, now used in scientific work throughout the world. The Fahrenheit scale is now also fixed by the freezing and boiling points of water. But the lower point is marked 32 degrees, and the interval between it and the boiling point is divided into one hundred and eighty equal parts, as explained in the preceding chapter.

The relations between these three scales are shown in Figure 6. Since between the freezing and boiling points of water there are 180 Fahrenheit, 100 centigrade, and 80 Réaumur degrees,

the Fahrenheit degree is five-ninths of the centigrade, and four-ninths of the Réaumur degree. To reduce centigrade or Réaumur temperatures to Fahrenheit, then, we must divide by 5 or 4 respectively and multiply by 9. Then since the Fahrenheight zero is 32 degrees below the zeros of the other scales, we must add 32 degrees to the result. For the converse conversion, we must first subtract 32 degrees, then divide by 9, and multiply by 5 or 4.

Scientific men are inclined to look down upon the Fahrenheit scale, and to feel that it has no further excuse for existence. But for common use I think it has some advantages. People are always exaggerating temperatures. If the day is hot, they add on a few degrees; if it is cold they deduct a few. No one ever gives the air temperature to a fraction of a degree, but only to whole degrees. Now on the Fahrenheit scale, on account of the small size of its degrees, these whoppers and inaccuracies are only about half as big as they are on either of the other scales.

Solids expand still less than liquids. The volumetric expansion of aluminum, which is one of the highest, is about half that of water at 70 degrees; that of iridium, the metal used on fountain pen tips and one of the least expansible, is about one-fourth that of aluminum. The expansion of platinum is about one-third that of aluminum.

Since we deal with solids mostly in the form of rods, beams, or wire, the changes in length are more important than those of volume. The fraction of its original length by which a bar elongates, when heated one degree, is called the *coefficient of linear expansion*. It is hence the *rate* of expansion—the expansion per unit of length and per degree rise in temperature. To get the total elongation of a rod, one must multiply the coefficient by the length of the rod and by the rise in temperature. Thus the coefficient for aluminum in metric units is 0.000025. To find the elongation of a rod 100 centimeters long when heated 100 centigrade degrees, we multiply twice by 100 and obtain 0.25 centimeters. Thus, a rod of aluminum, when heated from the freezing to the boiling point of water, will expand about one-tenth of an inch per yard. For a body that expands equally in all directions, the volumetric coefficient is three times the linear.

In all accurate work, measuring scales must be corrected for

linear expansion. Wood expands much less than metal, but swells considerably with moisture, and in a very uncertain fashion. Hence accurate measuring scales are always made of metal. Though the expansion is greater, the rate is known, the temperature is easily measured, and corrections can be applied.

It is a curious thing about alloys that their physical properties do not always fall midway between those of their ingredients, but sometimes much above or below any of them. The coefficients of expansion of steel and of nickel, for example, are

FIGURE 7

FIGURE 8

FIG. 7—TEMPERATURE COMPENSATION
FIG. 8—HARRISON'S GRIDIRON PENDULUM

about the same and equal to 0.000013. If these two metals are mixed in varying proportions, the expansion of the alloy is always less than that of either ingredient, and with 36 per cent nickel reaches a minimum that is one-fourteenth of the expansion of either ingredient alone. Alloys of nickel, steel, and other ingredients can now be made, whose expansion is practically nothing, or even negative. That is, a metal can be produced which actually contracts, though very little, when heated. These alloys are called "invar." They have been

used for measuring scales, for pendulum rods, and for other purposes.

Although linear expansions are small, when pieces of great length are used, the *total* elongations may become considerable. For this reason, rails must not be laid closely end to end, but with little gaps between them to allow for expansion. For a rise in temperature of 100 degrees Fahrenheit, a thirty-foot steel rail expands about one quarter of an inch. In winter we may hear the wind singing through the telegraph wires in rather high pitched tones, for the wires are then taut. In summer we do not hear these high notes, for the wires are then slack.

FIGURE 9   FIGURE 10

FIG. 9—MERCURY COMPENSATED PENDULUM
FIG. 10 BENDING THERMOSTAT

They must be strung, in fact, with sufficient sag to allow for the contraction in winter. The Eiffel Tower is six inches taller in summer than it is in winter when the thermometer may be 90 degrees lower. A long steel bridge span must have at least one end set on rollers to allow for expansion and contraction. If one observes the pipes laid along the walls of the New York subway or elsewhere, he will notice at intervals a crook shaped like the Greek letter Ω. This is to allow for expansion and contraction which simply close and open the crook. Where long rods or wires are used to operate signals or switches, they are interrupted at intervals by a complicated system of levers, which compensate for temperature changes which would otherwise move the signals.

Temperature compensation can be very exactly effected by using two metals of different expansibilities. Suppose it is desired to connect the two pieces *A* and *B*, Figure 7, in such a way that the distance between them shall remain invariable. We can connect them by means of the zigzag rods shown. If the expansibility of the middle rod is about twice that of the outside ones, then the upward expansion will be equal to the downward. This principle was applied by John Harrison in 1726 in his "gridiron pendulum" for clocks. This consisted of a pair of such zigzags, in order to obtain a symmetrical suspension, as shown in Figure 8. If compensation is not applied, the clock will run more slowly in hot weather because of the longer pendulum.

Another way of applying the same principle is shown in Figure 9. Here the pendulum bob consists of two little tubes partly filled with mercury. The upward expansion of the latter compensates for the downward expansion of the pendulum rod, thus keeping the effective length of the pendulum the same at all temperatures.

Another way of utilizing two metals of different expansibilities is to solder or weld two strips of them side by side. When the temperature changes, the different expansions cause the compound rod to bend. This device is much used in thermostats for temperature control. For example, in an automatic water heater, when the water reaches a certain temperature, the thermostat will bend over, and close an electric circuit as shown in Figure 10. This shuts off the gas. When the water cools a certain amount, the thermostat bends the other way and closes another contact which turns on the gas. The device is used also for small, flashing electric signs, the heating in this case being done by the electric current itself. By a device of this sort, a considerable movement can be produced by a small change in temperature. It is therefore more sensitive than one that depends upon direct elongation and contraction.

This method was also employed by Harrison in 1735 to compensate the balance wheel of a chronometer. A modification of his method is now used on all fine watches. A modern compensated balance wheel is shown in Figure 11. The rim consists of two branches, one end only of each being fixed to the opposite ends of a single spoke. These branches are composed of two metals, the more expansible one being on the outside.

Consequently, when the temperature rises, the arms bend inward. This compensates for the increase in inertia, and consequent slowing of the watch that would result from the expansion of the wheel. The elasticity of the hairspring also decreases as the temperature rises, and this would likewise slow the watch, so that the bending inward must be sufficient to compensate for this effect as well. The little weights that are screwed into the rim will be found to be quite irregularly spaced.

FIGURE 11   FIGURE 12

FIG. 11—COMPENSATED BALANCE WHEEL
FIG. 12—METALLIC THERMOMETER

This is because, when adjusting the compensation, the watch-maker moves them toward or away from the ends of the arms, according as the compensation needs to be increased or decreased.

The expansion of solids being small, it is not very suitable for measuring temperature. However, by coiling up a thin strip in the manner of a hairspring, a considerable length can be obtained, which will coil up or uncoil as the temperature changes. This can be made to move a needle around a dial, as shown in Figure 12. Thermometers have been made in this way. They have the advantage that the dial can be read across a room, so that it is not necessary to get up close and hunt for an almost invisible mercury thread.

A glass vessel breaks when hot water is poured into it, because the interior expands before the heat can be conveyed through the poorly conducting material to the outside. Chemists' glassware is made very thin on this account. While mechanically weak, it is thermally strong. Porcelain is about one-third as expansible as glass, and so stands the heat better. We have

no fear about pouring boiling water into a teacup.   Pyrex glass
is still less expansible, and will stand the heat of an oven.   The
most·remarkable substance in this regard, however, is fused
quartz, whose expansion is almost negligible, being twenty
times less than that of ordinary glass.   A red-hot vessel of this
substance can be plunged directly into cold water without
cracking.   Unfortunately, however, the substance is very
costly.

Like many familiar sayings, the assertion that all bodies
expand when heated, is not true.   Some contract.   We have
already mentioned invar, certain grades of which contract.
Many bodies do not expand equally in all directions.   Notably,
wood expands much more along the grain than it does across.
On the other hand, when it soaks up moisture, it expands mostly
across the grain.   Many crystals expand unequally in different
directions, and some even con-
tract along certain axes.
Stretched rubber contracts
when heated, as may be shown
by suspending a small weight
by a long rubber band and
bringing a hot flatiron near the
band.   The weight will then
rise.   Iron expands continuously
up to 1650 degrees Fahrenheit,
a bright red heat, then contracts
a bit, after which the expansion
is resumed as the temperature is further raised.   The reason is
that at the temperature mentioned, the *recalescence* point as it
is called, a change takes place in the arrangement of the mole-
cules in the iron crystal, and the new arrangement is more
compact than the old one.   Many substances have several of
these recalescence points.   Alloys show anomalies in the
neighborhood of the melting point of each ingredient.   Finally,
no substance expands at a uniform rate, but usually the rate
increases as the temperature rises.

Of all substances, liquids show in their expansions the great-
est departures from uniformity.   Water contracts as the
temperature is raised from the freezing point to 40 degrees
Fahrenheit, at which point it reaches a minimum volume or a
maximum density.   From there on, it expands up to the boiling

FIG. 13—THE EXPANSION OF WATER

point. The manner of its expansion is shown in Figure 13, in which the volumes are plotted vertically and the temperatures horizontally. The expansion is represented by a *curve*, which is concave upward. This shows that the positive rate of expansion increases continually from the freezing to the boiling point. If the expansion were uniform it would be represented by a straight line.

All liquids, when measured on the gas or thermodynamic scales of temperature, show similar upward curving expansion lines. Not all show a minimum volume like water, but in many cases, if the expansion line is continued downward—*extrapolated*—below the solidification point, it shows that such a minimum volume would have been reached had the substance not meanwhile solidified. Indeed, it is sometimes possible to prevent solidification, to undercool the liquid, as will be explained later, and reach this point

Mercury is no exception to this rule. When compared with the thermodynamic scale, it too shows an upward curving expansion line, though fortunately its curvature is very slight. When we use mercury to measure temperature in the manner already described, we arbitrarily make its expansion line straight. All the others become curved in comparison. If we make alcohol standard, then its expansion is made straight, and, compared with it, that of mercury becomes curved the other way, and all the others curved one way or the other. Hence no liquid is, as we have pointed out, a perfect temperature measurer.

But solids also show nonuniform expansions, and oftentimes many more or less sudden and considerable irregularities such as recalescence points. Even gases are not quite uniform, so that, in the end, no material substance is ι perfect temperature measurer. Only Kelvin's thermodynamic scale meets this requirement.

III

THE PERFECT GAS

THE expansion of a solid or of a liquid when heated is a comparatively simple matter, because it depends only upon the temperature. But the volume of a gas depends also upon the pressure. Liquids and solids, to be sure, are also affected by pressure, but enormous changes in pressure are required to produce very small changes in volume. Hence these effects can usually be neglected. But gases are very compressible and the pressure must be taken into account.

As the mathematician would say, the volume of a gas is a function of *two* variables, instead of only one, as is the case with a solid or a liquid. We can study the separate effects of either variable by keeping the other one for the time being constant. We shall first study the relation between volume and pressure when the temperature is kept constant.

This was first done in 1660 by Robert Boyle in a paper called "New Experiments Physico-Mechanical touching the spring of the air and its effects," and by Mariotte in 1676. They found, very simply, that when the pressure is doubled the volume is halved, and when the pressure is halved the volume is doubled, and so on. In short, the volume varies inversely as the pressure, so that the product of the two is constant. This is known as Boyle's or Mariotte's law.

If we plot this relation graphically, by laying off the pressures on a vertical scale, and the corresponding volumes horizontally, thus making a *pv* plot as it is called, we obtain the curve of Figure 14. This curve is known mathematically as an equilateral hyperbola. It has this property—that if from any point *P* on the curve perpendiculars are dropped on the two axes, the area of the rectangle formed by them and the portions of the axes they intercept is constant. For the two perpendiculars represent the pressure and the volume corre-

sponding to P, as shown in the diagram, and the area of the rectangle is equal to their product, which by Boyle's law is constant.

We can draw some curious conclusions from this curve. Suppose the point P to slide down the curve indefinitely toward the right. The rectangle then becomes continually longer and thinner, representing the increase in volume and corresponding decrease in pressure of the gas. But the area of the rectangle remains always the same, for it is equal to the constant product

FIG. 14 COMPRESSION OF A PERFECT GAS

of p and v. However long the rectangle becomes, it must still have some width. This is equivalent to the assertion that a gas expands indefinitely, that if introduced into a vacuum it will eventually fill the whole space, even if this be as large as the universe; and it will still exert a pressure on whatever boundaries there may be; that is, no matter how much the gas may have already expanded, it will still possess the power of further expansion. Thus the curve approaches the volume axis *asymptotically*: it gets nearer and nearer but never touches the axis—unless we grant that it does so at infinity. The rectangle then becomes of infinite length and infinitesimal width, but still has the same unalterable area. We leave it to the mathematicians to figure that out—if they can.

On the other hand, suppose we push the point P up the curve by compressing the gas. The laws tells us that no matter how many times we double the pressure, we shall always halve the volume, obtaining successively one-half, one-quarter, one-

eighth, . . . of the original volume—a geometrical series that ends (after an infinite number of terms) in nothing. According to the law, then, the volume of a gas can be indefinitely reduced; it can be squeezed out of existence.

We cannot believe that any real gas will act in either of these ways. However well Boyle's law may represent its behavior for middling values of pressure and volume, it cannot hold for extreme values. Somewhere the law must break down and be replaced by other laws. Boyle's law, in fact, assumes that a gas is all spring and no substance, that it is nothing but a pressure and a volume connected by a mathematical relation. But a real live gas is composed of molecules, of bits of what we may call solid matter. The pressure on the walls of a container is the summation of the individual pushes of all these separate particles. So long as the gas is fairly dense, the pressure will be sensibly uniform, and we cannot detect its spottiness. We can then treat the gas *en masse*, as though it were a continuous substance, or, if you prefer, as if it were composed of an infinite number of infinitesimal molecules. Then, and then only, can we lay down a rule like Boyle's for its *mass* behavior. But when the gas is greatly attenuated, so that its molecules are far apart, the pressure becomes a flickering and indefinite thing, to which no mass rule can be applied. A different and more complicated pattern of behavior must then replace the simple rule of Boyle.

Compression of a gas consists in pushing its molecules closer together. If the molecules have finite size, and we believe they have, this sort of compression can go on only until the molecules are brought into contact. We would not nowadays insist that compression must then absolutely stop. We no longer believe the molecules to be absolutely hard little pellets of unalterable size, as was once supposed. But it is likely that compression of the molecules themselves will be much more stoutly resisted than the mere pushing of them together. At this point, then, a different law of compression must supersede that of Boyle; and the change may be quite abrupt, like banging into a stone wall. In short, the substance should then act more like a liquid or a solid than a gas, in that an enormous increase in pressure will produce only a trifling decrease in volume. We cannot believe, then, that an actual gas can be squeezed out of existence. There must be a minimum volume that can only be further reduced by shattering the molecule.

Nevertheless, Boyle's law is very closely followed by many gases over wide ranges of pressure and volume. From this we may at once conclude that their molecules are very minute, exceedingly numerous, and ordinarily quite far apart—for they do not make their presence evident until very high pressures or enormous volumes are reached.

Indeed, for more than a century and a half Boyle's law was held to be absolutely true, and any doubts about it were regarded as a sort of scientific heresy. Nature was supposed to be essentially simple, and her laws to be the simplest possible. No simpler law than that of Boyle connecting the pressure and volume of a gas could be imagined. Hence it was concluded that it *must* be true. And when the first evidences of deviations from it at high pressures came from Despretz in 1827, and from Dulong and Arago in 1829, they were laid to experimental errors. But in 1847 Regnault, by very accurate experiments in which he compressed the more common gases up to 125 atmospheres (1875 pounds per square inch), established beyond doubt the existence of definite and progressively increasing deviations as the pressure rose.

And so the dogma of nature's simplicity received a severe body blow; and it has been badly pommeled ever since, until now a complete knock-out seems to have been achieved by Einstein.

In fact, nature is furiously complicated. But man's capacity is limited. Hence he seeks the simplest formulae. Although no part of the behavior of any gas conforms exactly to Boyle's law, it is convenient to use this law as a first approximation, and to describe the real ways of gases by their departures from it. Luckily this first approximation is frequently so close that no further corrections are necessary. The method is a common one in science. Thus, the astronomer assumes as a first approximation that the path of a planet is a perfect ellipse, although he knows that perturbations exist.

And so we have created the fiction of a *perfect gas*, which is simply one that obeys Boyle's law exactly for all pressures and volumes. Such a gas sets a standard of behavior for all other gases. It is always a gas. It cannot be liquefied. Its properties cannot in the least be altered by any amount of expansion, or by any excess of pressure. But obedience to Boyle's law is not the only demand that we shall make of it.

Having now settled the relation between pressure and volume, at least for a perfect gas,' when the temperature is kept constant, we proceed to investigate the effects of a temperature change when either the pressure or the volume is kept constant. Often it is not possible to keep the pressure constant throughout the whole of an experiment, but it suffices to bring it back at the end of the experiment to the value it had at the beginning. This requirement was met in Hero's early experiments. The air was heated in an open flask, and consequently was at atmospheric pressure when the flask was sealed. When the cooled flask was inverted and opened under water, the liquid flowed in until the pressure of the air within was again one atmosphere. This amounts to measuring the contraction under constant pressure. But during the cooling, the pressure of the air in the sealed flask must have diminished. Otherwise the water would not have been sucked up. Hence when the *volume* is kept constant, a change in temperature produces a change in pressure.

A gas therefore has two temperature coefficients. One expresses the change in volume when the pressure is kept constant—this is the ordinary coefficient of expansion, such as we used for liquids and solids; the other expresses the change in pressure when the volume is kept constant. They are called the *volume* and the *pressure coefficients*, respectively.

By a method substantially the same as Hero's but more refined, Gay-Lussac in 1802 measured the two coefficients for the more common gases. He obtained the surprising result that all these gases expanded equally. Also their pressures increased equally when they were heated at constant volume. And finally the volume and pressure coefficients were equal. Thus each gas, when heated from 0 to 100 degrees centigrade at constant pressure, expanded by 37 per cent of the volume it had at 0 degree. Similarly, if heated at constant volume between the same two temperatures, its pressure increased by 37 per cent of its zero degree value. He found also that both the volume and the pressure increase between these limits was uniform, as nearly as he could determine with a mercury thermometer.

These relations are now called Gay-Lussac's law, though in England they are frequently credited to Charles, because the latter claimed to have known them as early as 1787, although he published nothing about them. If they are true, then, if we plot the volume against the pressure—a *vt* plot as it is called—

the expansion of a gas at constant pressure is represented by a straight up-sloping line as in· Figure 15. The part *FB* represents the expansion from 0 to 100 degrees as measured by Gay-Lussac. At *B* the volume is 37 per cent greater than it is at *F*, or, using the more accurate figure of Regnault, 36.6 per cent greater. The expansion per degree is then 0.00366. Expressed as a common fraction, this figure is 1/273. A gas expands, then, 1/273rd of its 0-degree volume for every degree

FIG. 15- EXPANSION OF A PERFECT GAS

centigrade it is heated. Conversely, it contracts by the same fraction for every degree it is cooled. At this rate, then, if the gas is cooled to −273 degrees, it will contract 273/273rds of its 0-degree volume, in other words, to nothing. The downward prolongation of *FB* must therefore hit the zero of the volume axis at −273 degrees, and since a gas cannot contract to less than nothing, this would indicate that we here reach the greatest possible cold —the *absolute zero*.

Since the pressure change, according to Gay-Lussac, is the same as the volume change, the very same diagram will represent this case also by merely interchanging *p* and *v*. It then becomes a *pt* plot, and shows that when a gas is cooled at constant volume to −273 degrees, the pressure is also reduced to nothing.

We cannot, of course, believe that the volume of a real gas can be reduced to nothing by any amount of cooling, any more than it could be done by any excess of pressure. Gay-Lussac's law therefore cannot hold at the extremes any more than Boyle's law can, and for the same reason. A real gas is composed of molecules of finite size, and has a minimum volume. There is no difficulty, however, in believing that the pressure of

a gas can be reduced to zero by sufficient cooling. If, as we believe, the pressure is due to molecular motions, the energy of which depends upon the temperature, then when the temperature is reduced to *nil*, the motions will cease. In fact, the pressure might then be reduced to less than zero, or become negative, that is to say, it would become reversed into a contractive force. For if, as we also believe, there are forces of attraction between the molecules, then when their motions cease, they would gravitate together without the help of an external pressure.

The validity of Gay-Lussac's law was also tested by Regnault with great care and exactness. He found that the permanent gases (so-called because once believed to be nonliquefiable), air, oxygen, nitrogen, hydrogen, followed the law very closely over considerable ranges of temperature. Of course the mercury thermometer could not be used in these experiments, not only because of its limited range, but also because of the nonuniform expansion of mercury. Instead Regnault used one of the gases itself as a thermometric substance, and thus compared the expansions of the gases among themselves. Incidentally he greatly advanced the art of gas thermometry. He found the volume and pressure coefficients of these gases to be all very nearly the same, very nearly constant, and very close to the value found by Gay-Lussac. It is a remarkable fact that if the coefficients for these gases (to which may now be added helium and argon) are measured between 0 and 100 degrees centigrade and then either the constant pressure or the constant volume lines thus determined are prolonged downward, after the manner of Figure 15, they all strike zero volume or zero pressure within a fraction of a degree of − 273 degrees, and this despite the fact now known that all these gases liquefy and solidify before reaching this temperature. At or near this temperature, then, must lie the absolute zero. This conclusion has been confirmed by Kelvin's thermodynamic scale, which has placed the absolute zero at − 273.13 degrees centigrade or − 459.6 degrees Fahrenheit. Temperatures measured up from this point are called *absolute temperatures*, and may be given in centigrade or in Fahrenheit degrees. Thus the absolute temperature of the freezing point of water is 273 degrees centigrade or 492 degrees Fahrenheit.

Gay-Lussac's law then is followed closely but not exactly by

the so-called permanent gases.   It is followed less closely by the
more easily liquefiable gases.. We therefore treat it in the same
way that we did Boyle's law, as a convenient first approxima-
tion, and add it to the requirements of our perfect gas.   Accord-
ing to this law too, a perfect gas is always gas.   It never
liquefies, however much it is cooled.   As we may see from
Figure 15, the volume increases in exact proportion to the
absolute temperature when the pressure is kept constant, and
the pressure increases in exact proportion to the absolute tem-
perature when the volume is kept constant.   A perfect gas
would therefore be a perfect temperature measurer, and either
the volume or the pressure change could be used for this pur-
pose.   Since the permanent gases follow the law closely, they
are *good* temperature measurers, much better than any liquid
or solid.

A perfect gas, then, must obey the laws both of Boyle and of
Gay-Lussac.   The two laws can be combined in the one state-
ment, that the product pv is proportional to the absolute tem-
perature.   If we give the temperature a particular constant
value, then the product pv is constant as in Boyle's law, and we
obtain a curve like that of Figure 14.   If we give the tempera-
ture a different, say a higher constant value, we get another
similar curve, but situated farther out from the axes.   Four
such curves are shown in Figure 16.   Since the temperature is
constant along each of these, they are called *isothermals*, or lines
of equal temperature.   Boyle's law is therefore the law of the
isothermals of a perfect gas.

In this figure are shown also a constant pressure and a con-
stant volume line.   The former is horizontal because, since the
pressures are measured upward, this line must maintain a
constant height above the base line, which represents zero
pressure.   The latter is vertical because volumes are measured
by horizontal distances from the left-hand axis, which repre-
sents zero volume.   It may be noted that the three isothermals,
which are drawn for 273 degrees, 546 degrees, and 819 degrees
absolute, which numbers are in the proportion one, two, and
three, cut off equal intervals on these, and on any other, con-
stant pressure or constant volume lines.   This is required by
Gay-Lussac's law.

It is evident that the state or condition of a gas depends upon
three variables, p, v, and T.   We have used three plots, the

pv, *vt*, and *pt* plots, to show the effects of varying two of these quantities, while the third was kept constant. But all three may vary together. To show all the effects of such a threefold variation, to unite all these separate plots in a single diagram, we must use three dimensions. We must lay off *p*, *v*, and *T* along the three edges of a cube that meet in a corner. This may seem a little difficult, but let us not be discouraged. The end will justify the pains.

We already have everything we need in Figure 16. Let us imagine a *T* axis that starts at the lower left-hand corner of this
FIG. 16—ISOTHERMALS OF A PERFECT GAS

figure, and runs directly away from the reader, that is, perpendicular to the plane of the paper. Then let us move back each isothermal along this axis a distance proportional to its absolute temperature. Or, if this is too much of a strain on the imagination, let us construct an actual model out of cardboard.

Cut out each isothermal including its pressure and volume axis from a separate piece, as is shown in Figure 17 for the middle isothermal of Figure 16. Then glue it to two rectangular pieces of cardboard, which are set up at right angles to each other like a half open book, and which represent the *pt* and *vt* planes respectively. The isothermal is to be set back from the front edges of these a distance proportional to its

absolute temperature, 546 degrees in this case. Thus we might make this distance 5.46 inches. The front edges hence represent the isothermal for the absolute zero. They are also the p and v axes, while the edges along which the two boards are joined give the receding T axis. The pressure, volume, and temperature of any point such as P on the isothermal are given by the distances marked p, v, and T, on the diagram. When we have similarly affixed the other isothermals, we obtain a skeleton of the model shown in Figure 18. Since isothermals could have been constructed for every other temperature, they would, when all packed together in this way, form a continuous
FIG. 17 CONSTRUCTION OF A MODEL

concave surface, which thins down to two sharp edges along the pressure and volume axes, respectively. We have cut the model off at the freezing point isothermal, the better to show its shape, and again at the 819 degrees isothermal; but the surface continues of course down toward the reader to the absolute zero, and indefinitely outward along the three axes.

Every point on this surface represents a possible combination of p, v, and T, for a perfect gas; and every point not on the surface represents an impossible combination of the variables for such a gas. We thus have a complete view of the proper behavior of a perfect gas.

If we look down upon this model from above, we see the

constant pressure line of Figure 15, with its bit from F to B that was measured by Gay-Lussac, projected upon the bottom or vt plane. Every horizontal slice of the model cuts out a similar constant volume line, which runs straight to the p axis, showing zero volume at zero temperature.

If we look at the model from the right, we see the constant

FIG. 18—MODEL FOR A PERFECT GAS

volume line, obtained from Figure 15 by interchanging p and v, projected on the pt plane at the left. Every vertical slice of the model running perpendicularly away from the reader cuts out a similar constant volume line, which runs straight to the v axis, showing zero pressure at zero temperature.

Every vertical slice parallel to the plane of the paper cuts out, of course, a pv plot. And so the three plots are *sections* of this single three-dimensional model.

This whole surface can be given by a single equation, $pv = RT$, in which R is a constant. It is called the *perfect gas*

equation, and R is the gas constant. Every set of values of p, v, and T that satisfy this equation gives a point on the surface, and every set that does not satisfy it gives a point that is not on the surface. In fact, the equation merely states that the product pv is proportional to the absolute temperature, which we have already said completely defines a perfect gas.

While R is constant for any one gas, it is different for different gases. In fact it depends upon the density of the gas, which in turn, according to Avogradro's law, depends upon the weight of the gas molecules. Hence, if all gases were perfect, they would differ only in respect to molecular weight. If R be given the values that correspond to the different gases, we obtain a sheaf of curved surfaces, each like the one of Figure 18, all springing from the p and v axes, like the sheets of a paper pad that are glued down along two edges, and are ruffled up at the free corner, the lighter gases being represented by the higher sheets. Since every element will become gas at some high temperature, there are at least ninety-two of these sheets. But there are also many compound gases. Every gas approximates to perfect behavior if the temperature is sufficiently elevated. Hence, every gas will have a sheet, and some part of its behavior will be more or less closely represented by some part of its sheet.

IV

THOSE CALORIES

A MAN once complained to the servant at his boarding house
that his room was cold. "The thermometer stands at only
fifty degrees," he showed her. "Ah! But for this little room,"
the maid replied, "forty degrees would be quite enough."

Whether the girl was ever brought to understand the differ-
ence between temperature and heat, I do not know; but I am
sure that no reader of this book would ever make a similar
mistake. Yet we often carelessly use the two terms inter-
changeably. We say, "The heat was terrible to-day," when
we merely mean that the temperature was uncomfortably
elevated. Yet it is perhaps not sufficiently realized that heat
is a *quantity*, just as much as a material substance is. Indeed, it
was at one time supposed actually to be a material substance,
an imponderable or weightless fluid, to which Lavoisier gave
the name *caloric*. The thermometer does not measure this
quantity. It measures only its intensity or degree of concentra-
tion.

If we place two bodies of different temperatures in contact,
they assume after a time the same temperature. We say that
heat has passed from the one to the other, and that the tempera-
ture of the one has fallen because it has lost heat, while that of
the other has risen because it has gained heat. We *observe* the
temperature changes, by means of thermometers or otherwise.
We *infer* the passage of heat as the cause of them.

Two bodies at different temperatures may be likened to two
vessels in which water stands at different levels, as in Figure 19.
The water represents a quantity of heat, and the levels repre-
sent the temperatures. When the two vessels are put into
communication, water flows from one to the other until the
levels are equalized. If there is no leakage, the quantity of
water that enters the one is the same as what left the other. If

the diameters of the vessels are the same and are uniform, the
level of the one rises as much as that of the other descends, and
the final level is halfway between.

But if heat quantity is not measured by a thermometer, how
then shall we measure it? The answer is—in the same way
that we measure water. And how do we measure water?
Why! We provide a vessel having a certain *capacity*, fill it to
the top, and then say, for example, we have a quart.

Let us put a kettle of water on
the stove and place a thermometer
in the water. If the fire is a gas
flame that burns at a steady rate,
we may assume that heat flows
into the water at a steady rate, and
we shall find that the rise in tem-
perature is also uniform. Equal
amounts of heat are added to the
water in each minute, and equal
changes in temperature occur each
FIG. 19 COMMUNICATING VESSELS

minute. If we fill the kettle half full, we shall find that the
boiling point is reached in half the time that the full kettle
required. The half quantity of water has therefore half the
capacity for heat that the full quantity had; it took half the
quantity of heat to fill it up, so to speak, to the boiling point.
The *heat capacity* of a body is therefore proportional to the
quantity of the body, or more exactly, as could be ascertained
by more precise experiments, to its mass or weight. In a given
weight of water, or of any other substance, we have then a
definite heat capacity. It requires a definite amount of heat to
fill it from one mark to another on the thermometer scale.

In measuring a liquid, we usually start with an empty vessel
and fill it to the top. We cannot do this with heat, for we
cannot empty a body of all its heat, that is, cool it to the abso-
lute zero. We have to start with the body already partly filled,
so to speak. We often do this in measuring liquids. Suppose
we have a graduated cylinder, as in Figure 20, already filled to
a certain mark with water, and we wish to add another quart.
We simply pour in water until the level rises to the mark that
indicates another quart. We do the same thing with heat.
Suppose we have a kilogram of water already filled with heat to
the o-degree mark on the centigrade scale, or 273 degrees

absolute. We add heat until the temperature rises to the
373-degree mark, and then say that we have added one
hundred *large calories.*

The large calorie is therefore the amount of heat required to
raise the temperature of one kilogram of water one degree on
the centigrade scale. This is the heat unit that overweight
women are so much concerned about, without perhaps knowing

FIG. 20 -- CALORIES AND QUARTS

just what it means. They tell us that an egg contains 75
calories. That means that, when completely oxidized or
burnt, it will develop enough heat to raise the temperature of a
kilogram of water 75 degrees centigrade, or to raise about a pint
and a half of water from the freezing to the boiling point.
These people unwittingly eat, or perhaps abstain from eating,
by the centigrade scale, but use the Fahrenheit in all their other
dealings.

For scientific purposes the heat unit most used is the small
calorie, which is the thousandth part of a large calorie. For
engineering purposes in English-speaking countries, the British
Thermal Unit, abbreviated to B.T.U., is mostly employed.
This is the quantity of heat required to raise the temperature of
one pound of water one degree on the Fahrenheit scale. We

shall call this unit a *therm*. It is equal to 252 small calories, or about one-fourth of a large calorie.

All substances do not have the same capacity for heat, weight for weight, that water has. The amount of heat required to raise the temperature of one gram of any substance one degree centigrade—or one pound, one degree Fahrenheit—is called the *specific heat* of the substance. Since the amount of heat required for this purpose in the case of water is the unit of heat, the specific heat of water is 1. All other specific heats are therefore expressed in terms of that of water. Being thus relative numbers, they are, like specific gravities, independent of the units employed in measuring them. The *thermal capacity* of a body is its specific heat multiplied by its weight. It is the total heat absorbed by the body when its temperature is raised one degree. Thus five pounds of iron will absorb five times as much heat as one pound of iron will, when both are heated the same number of degrees.

Let us take a pound of boiling water at 100 degrees centigrade, and mix it with a pound of cold water, at, say, 10 degrees centigrade. The mixture will assume a temperature of 55 degrees, just halfway between the extremes. The hot water has cooled 45 degrees, while the cold water has warmed 45 degrees, and of course the heat lost by the one is the same as that gained by the other, barring any loss during the transaction. This is illustrated by our communicating vessels of Figure 19 when their diameters are equal. The one level, as we explained, then sinks as much as the other rises.

Suppose, now, that instead of a pound of water at 100 degrees, we introduce a pound of iron at 100 degrees into our cold water. The final temperature of the mixture will then be 20 degrees. The iron has fallen 80 degrees, while the water has risen only 10 degrees, in receiving the same amount of heat that the iron lost. The heat capacity of the iron is therefore only one-eighth that of the equal weight of water. Its specific heat is 0.125. This case would be illustrated by communicating vessels in which the diameter of one was only one-eighth that of the other. The level in this one then sinks eight times as much as that in the other one rises. The diameter of the vessel hence corresponds to the specific heat.

Now the diameter of a vessel might not be uniform. That would mean that the specific heat of a substance might vary

with the temperature. That has been found to be the case. The heat absorbed by a gram of water between 0 and 1 degree centigrade is not the same as that absorbed between 15 degrees and 16 degrees. Hence, in defining the calorie, we must for exact work specify the two temperatures between which the one-degree rise in temperature is to take place.

The specific heats of nearly all substances are less than that of water, and hence are expressed by decimal numbers. Solids are particularly low, all the common substances ranging from 0.031 for lead to 0.22 for aluminum (from 1/30 to 1/5). Ice, however, is an exception with a specific heat of 0.5. There are also some less common substances with high specific heats. That of lithium, for example, at ordinary temperatures is 0.84, and increases rapidly with the temperature, so that above 100 degrees centigrade, the specific heat of this metal is greater than that of water. This is very exceptional. The noble metals, gold, mercury, platinum, iridium, tantalum, tungsten, on the other hand, all have low specific heats around 0.03.

Liquids in general have higher specific heats than solids. They range mostly around half that of water. Mercury, however, follows rather the rule for the noble metals with a specific heat of only 0.033. This low thermal capacity of mercury is another quality that adapts it for thermometers. It abstracts but little heat from the body whose temperature is to be measured.

Water, on account of its high thermal capacity, is an excellent storehouse of heat. No better substance can be found with which to fill your hot water bottle. The great quantity of heat contained in the ocean, and particularly in its warmer currents, has a marked effect in equalizing the climate. On the coasts, the extremes of temperature are much less than inland. For the same reason, water is the best cooling agent. In the radiator of an automobile, or in the condenser of a steam plant, it will carry away more heat per pound than any other liquid.

When it comes to gases, we find that just as they had two co-efficients of expansion, so they have also two specific heats, according to whether the pressure of the volume is kept constant during the heating. The specific heat of a gas is very difficult to measure with accuracy, for since the heat capacity of a body depends upon its weight, and a gas is very light, an

enormous volume is required in order to absorb an appreciable and accurately measurable amount of heat. The difficulty is not so great in the case of the specific heat at constant pressure, for in that case the hot gas may be allowed to stream through a coil of pipe immersed in the water of a calorimeter, the rise in temperature of the water and the fall in temperature of the gas as it passes being simultaneously measured. In this way a large volume of gas can be used. By this method Regnault in the middle of the last century made the first accurate and extensive measurements of the specific heats of gases at constant pressure.

In the case of the specific heat at constant volume, however, a fixed quantity of the gas must be confined in a closed container, and this cannot be very large. Now even the lightest possible container will be many times heavier, and will therefore absorb many times more heat than the enclosed gas will. It is necessary first to determine how much heat the container absorbs without the gas, and then how much it absorbs with the gas. The difference between these two large and nearly equal quantities gives the amount of heat the gas alone absorbs. This is like trying to weigh a feather inside a leaden casket, by weighing the casket with and without the feather. Suppose we commit an error of one part in a thousand in weighing the casket. If the casket weighs a hundred times as much as the feather, then the error in the weight of the feather will be one part in ten or 10 per cent. Because of this difficulty, direct and accurate measurements of the specific heats at constant volume were not made until 1890, when Joly invented a new kind of "differential" calorimeter for the purpose. Even to-day but few gases have been measured in this way. Fortunately, however, we have indirect ways of calculating these specific heats from other data. But this matter is too complicated to discuss here.

The specific heats of the permanent gases at constant pressure are all much the same, and range from one-half to one-eighth. That of air is 0.24. Hydrogen, however, is a great exception, having the enormous value of 3.40. This is the only substance that has a decidedly higher specific heat than water. This undoubtedly accounts for the high thermal capacity of water, which contains considerable hydrogen. The specific heat of steam is 0.47, that of ice 0.5, so that water when it

becomes either vapor or solid loses about half of its thermal capacity.

The specific heat of a gas at constant volume is always less than its specific heat at constant pressure. For example, the former for air is 0.17, that for steam is 0.34, for hydrogen 2.40. Comparing these with the corresponding values for constant pressure given above, they are all seen to be less. The reason for this long remained a profound mystery, until J. R. Mayer in 1842 propounded the theory that heat is a form of energy, that a calorie will produce a definite number of kilogram-meters of work—a therm, so many foot pounds—and *vice versa*. He pointed out that when a gas is heated at constant pressure, it expands and does work against the opposing atmospheric pressure. A certain amount of heat is required to raise the temperature of a gas one degree at constant volume. This is its real specific heat. A certain additional amount of heat is required at constant pressure to do the work of expansion. From this additional heat, and the work done, he showed that the number of kilogram-meters produced by the consumption and disappearance of one calorie—what we now call the *mechanical equivalent of heat*—could be calculated. This is the principle of the conservation of energy. A year later Joule independently discovered this principle, and made the first direct experimental measurements of the mechanical equivalent. These have been often repeated and refined by Rowland and others. The accepted value to-day is 778 foot pounds to one British Thermal Unit.

By the work of Joule, Kelvin, Clausius, Tyndall, and others, it was further established that heat is a form of molecular agitation, or as Tyndall put it, "a mode of motion." This is the mechanical or kinetic theory of heat. Although it had been often proposed long before, it was only established after a long and bitter struggle with the official caloric theory. But that is another story.

V

LATENT HEAT

ONE morning, the author of these pages complained to the cook that his coffee was not very hot. She replied: "Well, I boiled it for half an hour and couldn't get it any hotter." We feel inclined to ask, "What's wrong with this picture?" While most persons may be aware of the fact that prolonged boiling does not raise the temperature of a liquid, nevertheless it is difficult to persuade any cook that to boil vegetables "hard" does not cook them any faster or any better, than to boil them gently. Yet with a thermometer it is easy to show that no matter how fierce the fire or prolonged the boiling, the temperature of the water cannot be raised above its boiling point, 212 degrees. Now, during the boiling the fire is continually delivering heat to the water. What becomes of it all? If the kitchen is small and not very well ventilated, we shall soon find out (especially if a thermometer hangs on the wall) what becomes of it. Certainly the heat that causes the cook to grumble about the hot kitchen doesn't do the vegetables any good—nor the cook, nor those who have to listen to her, nor the one who has to pay the gas bills.

The heat supplied to the water serves merely to maintain its temperature. Except for a small amount required by the chemical changes that constitute cooking, all of it goes to make up the losses to the surroundings. If these could be prevented, and they can be greatly reduced by efficient heat insulation, such as that of the fireless cooker and the electric oven, a surprisingly small amount of heat would do the cooking. Our open pans, iron stoves, and uninsulated ovens are a disgrace to an age that calls itself scientific. The only good that violent boiling can do is to maintain a lively circulation of the food. But it is cheaper to do this with a spoon.

Let us put a kettle of ice-cold water on a steady gas fire and

see how long it takes to boil.   We shall find that it takes more
than five times as long to boil all the water off as it did to heat
the water from the freezing to the boiling point.   And since the
fire has burned steadily all this time, it must have delivered
more than five times as much heat to the kettle during the
boiling as during the heating period.   Yet all this fivefold
quantity of heat did not raise the temperature of the water one
jot.   Neither did it raise the temperature of the steam.   If we
place a thermometer in the steam just above the liquid, we shall
find that it again stands at 212 degrees during the whole of the
boiling.   Only when the last drop of water has boiled off, can
the temperature of the steam be raised.   Then the temperature
rises with sudden and alarming rapidity, and if the fire is not
immediately extinguished, the kettle will burn.

That all this heat that produced no rise in temperature has
not somehow gone out of existence, but is still in the steam, we
can prove by getting it out of the steam again.   If, instead of
allowing the steam to escape and cause the cook to grumble, we
had conducted it by means of a hose to a coil of pipe immersed
in a large body of cold water, the steam would have condensed
in the pipe and raised the temperature of the surrounding
water.   In fact, we could in this way recover from the steam
more than enough heat to raise the temperature of five similar
kettles full of water from the freezing to the boiling point, in
short, all the heat that we had put in.

More exact measurements show that to boil one gram of
water at 100 degrees centigrade and convert it into steam at the
same temperature, requires 538 calories of heat, whereas to
raise the temperature of a gram of water from 0 degree to 100
degrees centigrade requires only 100 calories.   And conversely,
by the condensation of that same steam at 100 degrees centi-
grade to water at the same temperature, provided there are no
losses, 538 calories of heat can be recovered.   Or to speak
English, the conversion of a pound of water at 212 degrees
Fahrenheit into steam at the same temperature requires 970
therms, whereas to heat the water from 32 degrees to 212 de-
grees requires only 180 therms.

This absorption by a boiling liquid of a large quantity of heat
was discovered by Joseph Black in 1757.   He called it the
latent heat of vaporization.   Since this heat did not raise the tem-
perature of the liquid, but could be recovered from the steam,

and was then as competent to raise the temperature of other bodies as heat derived from any other source, Black supposed that it must meanwhile have existed in some sort of inactive or *latent* state.

Steam at 100 degrees centigrade then, contains a great deal more heat than water does at the same temperature. This explains why a severe burn is produced by steam, and very little by boiling water. The water in cooling from 100 degrees centigrade to the temperature of the skin, 37 degrees centigrade, gives up only 63 calories per gram. But the steam in condensing and cooling to the same temperature gives up over 600 calories.

Steam is therefore very useful for heating purposes. But while a pound of steam contains over six times as much heat as a pound of water at 212 degrees Fahrenheit, both being measured up from the freezing point, the steam requires sixteen hundred times as much space as the water. A volume of water equal to that of the steam would contain two hundred and fifty times as much heat as the latter. Hence, for storage of heat, water is better. It is still the best thing to put in your hot water bottle, because you can get so much more in a given space. Steam is suitable for heating when there is always a direct connection with the boiler, and new steam can be continuously supplied as fast as the old steam is cooled and condensed. Since steam travels very fast –fourteen hundred feet or more per second, depending upon the pressure—heat can be delivered in this way very rapidly.

The 538 calories per gram that water requires for its vaporization is more than is required by any other liquid. The latent heat of mercury is only 63 calories, that of alcohol 207, of gasoline 95 calories. It may be interesting to note that the liquefied gases have the following latent heats: hydrogen 123, oxygen 58, nitrogen 50, air 50, and carbon dioxide 57 calories per gram. Although hydrogen is higher than the rest, it is not nearly so exceptional in this matter as it is with respect to its specific heat. And none of these figures even approaches that for water.

A considerable amount of heat is also absorbed during a change from the solid to the liquid state, though not as much as during vaporization. This absorption of heat can be demonstrated in the following way. Let us fill the inside container of

an ice cream freezer with water, and having inserted a thermometer, surround it with the usual mixture of ice and salt. With one part of salt to. three of finely shaved ice, this mixture can be made to reach a temperature as low as 0 degree Fahrenheit, and if renewed from time to time can be kept at that temperature. The temperature of the water in the container descends gradually until at 32 degrees the descent stops. Freezing has now begun, and during the whole of this process, provided the mixture of ice and water is constantly stirred, the temperature remains stationary at 32 degrees. When at last all of the water is frozen, the temperature again descends. The ice becomes colder, and approximates finally the temperature of the surrounding freezing mixture. During the whole of the rather prolonged period of freezing, heat must have been continually withdrawn from the water by the colder surroundings. This is the *latent heat of fusion.*

If now we remove the can from the freezer and expose it to the warm surroundings, the reverse processes take place. The temperature of the ice rises until 32 degrees is reached, and melting begins. During this process, the temperature again remains stationary, and, if the ice and water are kept well stirred, will not rise until the last bit of ice has melted. Then the water warms up, and approaches the temperature of the surroundings. During the long melting period, heat must have been continually absorbed from the warmer surroundings, in fact, as exact measurements would show, the same amount of heat as was withdrawn from the water during the freezing. These facts were also discovered by Black in 1757.

The latent heat of fusion of ice is 80 calories per gram, or 144 therms per pound. Almost no substance has a higher value. Mercury requires for its melting only 3 calories per gram, lead 5, and aluminum 77.

Before the facts of latent heat were discovered by Black, it was supposed that the rise in temperature of a substance through its melting point was continuous, and that no more heat was required than for a similar rise in temperature elsewhere along the scale. If this were so, Black said, the consequences would be frightful. It would mean that when a block of ice had reached the melting point, the addition of a very small amount of heat would convert the whole mass almost at once into water. Instead of this, we observe that ice, even

when exposed to quite high temperatures, melts slowly and only on the surface, and does not rise above the melting point until it is all melted. Even as things are, Black said, the melting of mountain snows is often sufficiently rapid to produce great torrents and floods. We may add that ice would be of no use in a refrigerator if a very little heat sufficed to melt it all at once.

VI

CHANGE OF STATE

DURING a change of state there is always a change in volume while the temperature remains stationary. This distinguishes it from the ordinary thermal expansion which takes place with a rising temperature. Figure 21, for instance, is a *vt* plot of ice, water, and steam. The proportion from 32 degrees to 212 degrees is identical with Figure 13, and shows the volume changes of water as the temperature varies between those limits. *At* those limits, however, the line rises vertically, showing expansions without change of temperature. At the boiling point the expansion is enormous, so great that it cannot be shown on the scale of this diagram. Hence the vertical line representing it is broken. A cubic inch of water at 212 degrees becomes nearly a cubic foot of steam, more exactly sixteen hundred cubic inches. If the height of the water line at this point were one inch, that of the steam line would be 133 feet. All liquids show similarly large expansions on vaporizing. The up slope of the steam line shows the resumption of thermal expansion with rising temperature after the liquid has vaporized.

The change in volume at the freezing point is much smaller, 10 per cent for water, and this is larger than for almost any other substance. The down slope of the ice line shows that the ice contracts as its temperature is lowered, just as any other solid does.

Although water and a few other substances expand on solidifying, most substances contract, and the volume change is usually very small. Paraffin wax, however, contracts considerably. If a pot of melted paraffin is allowed to cool, a deep depression forms at the center of the surface, and resembles the dimple at the top of an apple. This occurs because the wax contracts and, solidifying first around the sides and bottom,

the surface is drawn down in the center. Bronze and brass contract very slightly. Aluminum contracts so much that good castings are difficult to make. Type metal expands slightly and, thus filling every corner of the mold, good sharp castings can be made.

Since water expands 10 per cent on freezing, a block of ice floats with nine-tenths below and one-tenth above the surface of the water. It is commonly said that an iceberg floats with one-seventh above the surface. This is partly because sea water is denser than fresh water, and partly because common ice is full of air bubbles which lighten it.
FIG. 21   EXPANSION OF ICE, WATER, AND STEAM

The expansion of water on freezing causes a good deal of damage. It bursts our water pipes, spoils fruits and vegetables by bursting their cells, cracks and disintegrates the rocks, thus promoting erosion and the removal of the soil to the sea, and a late spring frost destroys the young buds and the sap. It seems to be an unmitigated nuisance. But if water contracted on freezing, the consequences would be far worse—in fact, disastrous. In that case ice, as soon as it formed on the surface of a pond, would sink to the bottom. The warmer water on top would be continually exposed to the freezing weather, and would continually freeze and sink. Before long the whole pond would be a solid block of ice. Many of our lakes, rivers, and harbors would freeze solid. In summer, the water that resulted from the first melting would cover the ice below and hinder the warmth from reaching it. And this hindrance would increase

as the melting proceeded, with the result that many of our frozen lakes and rivers would never thaw out. The polar caps would extend into and cover most of the temperate zones, the glaciers would descend deeper into the valleys, and the climate of the whole world would become so frigid that only the equatorial regions would remain habitable.

But since ice floats, it remains on the surface and hinders the heat from flowing out of the water below. And the thicker the ice the greater the insulation. The consequence is that a point is reached where further freezing cannot take place, however severe or prolonged the cold. Even in the polar regions ice never directly freezes to more than six or seven feet in thickness. Where it is thicker, it is because it has been piled up in jams, or has slid down from the land as glaciers, or because snow has fallen on it and congealed to ice. In summer the water resulting from the first melting, being heavier, seeks every crack and crevice to get under the ice. Thus a fresh surface of ice is always exposed to the melting rays of the sun. The fact that ice floats thus hinders freezing in winter and promotes melting in summer, thereby preventing great accumulations of ice, which, so to speak, store up the cold of winter, and require a good portion of the summer's heat to thaw them out.

We have seen that in general, when heat is steadily poured into a solid, its temperature rises and its volume increases continuously. But at the melting and boiling points discontinuities occur. At each point, there is a change in volume without change in temperature, and the absorption or rejection of a latent heat. These are the two essential characteristics of a change of state.

In Chapter II we mentioned that iron expands up to 1650 degrees Fahrenheit, and then contracts a bit. If a very hot piece of iron is allowed to cool, the glow gradually diminishes until this point is reached. Then it brightens up for a moment, after which the fading is resumed. It is because the iron thus seems to reheat itself a bit, that this point is called the recalescence point. There is a pause or discontinuity in the temperature drop, the release of a latent heat, and, as we saw in Chapter II, a change in volume. In short, we have here all the characteristics of a change of state, so that what happens has just as much right to this title as those larger and more

conspicuous changes from solid to liquid and from liquid to gas, with which we are more familiar.   We shall see that these minor changes of state are quite common.   And this change at recalescence we saw was due to a rearrangement of the molecules.   This is, in fact, the essential cause of *all* changes of state.

A change in molecular arrangement involves a change in molecular forces.   When the molecules are separated, these forces are attractive, diminish rapidly with the distance, and at a short distance become insensible.   Since we no longer conceive the atom as a solid mass of matter, but as made up of exceedingly minute protons and electrons and hence nearly all space, and the molecule is a collection of atoms, we have to adopt some convention as to what shall constitute the boundary of a molecule.   When the distance between the centers of two molecules is reduced to a certain amount, the attraction is more or less suddenly replaced by a repulsion, which increases very rapidly as the distance is further diminished.   We can only say that the point where this inversion of force occurs is on the boundaries of both molecules, and the two are then in contact.   After all, this is all we could say even if the molecules were solid particles.   Any closer approach means that the boundaries must be pushed in, the molecules themselves compressed.   This is resisted in the same way that an elastic body resists compression.   When the compressing force is removed, the boundaries spring back into shape, so that when two molecules collide they rebound like elastic bodies.

In the solid and liquid states, the molecules are, as we have said, in contact or nearly so.   Hence in these states bodies stoutly resist compression, which would largely consist in compression of the molecules.   They also resist tension, or the separation of the molecules.   Hence both solids and liquids have definite volumes, which can only be altered by force, or by change of temperature.   The mean distance between the molecular centers is conserved.

In the solid state, furthermore, each molecule is held to a fixed position, and any effort to displace it is resisted.   If a molecule is forcibly displaced, but not too much, it springs back to its original position.   Now a change in the volume of a body involves only a change in the distances between the molecules, but a change in shape requires changes in their relative positions.   Since these are resisted, a solid resists change of

shape. It has, as we say, *rigidity* or *form elasticity*. When deformed, if not too much, it springs back into shape.

No liquid is springy in this way. Its molecules slide easily over one another like slippery fish eggs, and none has a definite place. Hence a liquid flows. It has no definite shape, but assumes that of the containing vessel and a level surface.

Every liquid, however, offers some resistance to this sliding of its molecules. The liquid may be thin and mobile like alcohol or water and flow easily, or it may be thick and *viscous* like honey or molasses and flow sluggishly. The former will very quickly assume the shape of the containing vessel and a level surface; the latter will require more time; but however viscous the liquid, it will eventually do these things. Viscosity is hence very different from the spring of solids, which eventually *stops* the displacement. Viscosity is a species of *internal friction* which *retards* the flow, but cannot stop it. So long as the force is applied, the flow continues, though it may be very slow. Thus molasses will continue to run down hill, even if the slope be gentle, so long as there is any hill to run down.

This flowing, which is so characteristic of liquids, can be induced, under certain conditions, in solids. If a sufficient force is applied to the molecule of a solid, it may be shifted to a new position. And if the force is not so great as to tear the molecule completely away from its neighbors, that is, to break the solid, then, when the force is removed, the molecule will adopt its new position and maintain it vigorously, just as it did the old one. In short, the piece has now received a permanent deformation or *set* as we call it, and is now springy with respect to the new form as it was with respect to the old one. Thus when a steel saw has become bent, it always springs back to the bent shape.

A force sufficient to produce a permanent set is said to exceed the *elastic limit*. If such a force—insufficient, however, to break the piece—is maintained, a continual shift or sliding of the molecules over one another will be produced, and will continue as long as the force is applied. This is a flowing of the substance precisely like that of a liquid. The only difference is that it is far more highly resisted. The viscosity of a solid is thus much greater than that of a liquid.

The distinction between a solid and a liquid therefore con-

sist not in the fact that a solid cannot flow, but in the fact that to produce a flow the force must exceed a certain amount, namely, the elastic limit. Loads up to this limit are *permanently supported*. Thus our columns and beams, if not overloaded, continue to hold up our buildings indefinitely. Solids thus possess a *limited* rigidity. Liquids, on the other hand, possess no rigidity. The smallest force will produce some flow, no matter how viscous the liquid. And the flow will continue, that is, the deformation will increase, as long as the force is applied.

In general, only a limited amount of flow can be produced in a solid without breaking it. When this amount is very small, the solid is said to be brittle; when it is large, the solid is ductile or plastic. Indeed, some solids seem to have no springiness at all, since they can be bent or twisted into any shape we desire. But they must have some, for otherwise they would not retain the shapes we give them.

Flowing always takes time. Every one knows that, in order to bend an object that is not very ductile, the job must be done slowly and carefully. The elastic limit must be exceeded, but the breaking point must not be reached. It is therefore often a ticklish business, which cannot be hurried.

Since to hold a molecule to a fixed place requires stronger forces, and hence a closer packing, than merely to hold it to a fixed distance, and some solids are less dense than their liquids, the rigidity of these solids must be due to a closer packing of the molecules in some places than in others. These strong parts run through the mass like the framework of a building. Hence a solid has structure. And the structure of a solid consists in having a place for every molecule, and every molecule in its place, except in so far as it is compelled by force to alter its place.

A liquid, instead, is structureless. No molecule has a definite habitation, but wanders from place to place. On the whole they are uniformly distributed, for which reason a liquid is *isotropic*, that is, has the same properties in all directions. Usually, also, it is clear or transparent, except when it is a metal, for all metals are opaque. A solid is usually *anisotropic* and opaque.

The structures of solids are of three sorts. In one type the molecules are arranged in a geometrical pattern, in straight

lines and planes that meet at very definite angles. This is the crystalline type. Such a solid has a definite melting point, fuses or solidifies bit by bit at a constant temperature while absorbing or rejecting a latent heat. This is the type we have already described.

In the second type the structure is irregular. In places the molecules are clumped together, in others more widely separated. The fracture of such a solid shows a grain, but no crystal facets. This is the *amorphous* or formless type. It includes such substances as fats, gums, resins, waxes. These solids have no melting points. When heated, they gradually soften throughout the whole mass, becoming first pasty, and then a thick fluid, which thins as the temperature is raised.

This sort of melting is similar to what all melting was supposed to be like before the days of Black, and which he said would be so disastrous in the case of ice. If heat is supplied at a constant rate, there is no halt in the temperature rise while a large latent heat is absorbed, as is the case with crystalline solids. However, there is a slowing up in the temperature rise, an increased rate of softening over a certain temperature range, so that while a definite latent heat cannot be assigned, more heat is absorbed along this range than along an equal range elsewhere on the scale. The whole change seems to be merely one of viscosity, which becomes more rapid in this neighbourhood. The nearest approach we can make to a definite melting point is to assign the point at which this change is fastest.

In fact these substances even in their so-called solid states are more like highly viscous fluids than like true solids. For the smallest force steadily applied will produce in them a continuous yielding or flow. Thus a stick of sealing wax supported at its two ends will gradually sag in the middle of its own weight, though the amount may be perceptible only after several hours, conspicuous only after several days. Much depends upon the temperature, for the viscosity of these substances varies greatly with the temperature. Wax candles will bend over and droop on a warm day until they are almost double. But if you try to straighten one up, you will surely break it, unless you are willing to spend an hour or so at the job. A penny placed on a piece of tar will gradually sink through it and the tar will close in over it.

In this connection the author may perhaps tell a little story

on himself.   He owned at one time a small house in California near an abandoned oil field.   The ground all about was covered with a layer of a tarry substance several inches thick. He wished to plant a garden in his back yard.   But it was necessary first to remove the tar.   At first he went at it energetically with a pickax, intending to break it up by main strength and stupidity.   After an hour's hard work, almost nothing had been accomplished.   Then he bethought himself of his. physics. "This is a tarry substance," he said.   "It will not yield to violence.   We must use persuasion."   So he drove his pickax under the edge of the tar, wedged a rock under the pick as a fulcrum, and stood on the other end.   For a minute or so nothing seemed to happen.   Then gradually the tarry layer rose, until at last a fine big piece broke off.   In this way the whole yard was finally cleared with less fatigue than the first hour had cost.   Thus it sometimes pays to know something — especially if you are lazy.

The third type of solid is still more formless than the preceding.   The molecules are uniformly distributed, precisely as in a liquid, but fixed in their positions instead of wandering.   Like the liquids, they are isotropic, and generally clear or transparent.   A fracture is smooth, and shows neither grain nor crystal facets.

But far from being soft and plastic like the amorphous bodies already discussed, these substances when cold are among the most solid of the solids.   They are extremely rigid, hard, and brittle.   They permit of scarcely any flowing at all.   Like the other amorphous bodies, they soften as their melting points are approached, but the softening does not begin until quite close to these points, and is then quite rapid.   They can then flow tremendously, and be drawn out into long fine threads.   These are the glasses, of which window glass is one variety.   The nature of these substances, however, will be discussed in Chapter XII.

Finally   in the gaseous states the molecules are so widely separated that they are most of the time quite beyond the effective range of their mutual attractions.   They only come within that range during the brief moments of collision, but immediately rebound and separate again.   They are on the whole uniformly distributed.

The mechanical theory of heat affords a ready explanation of

these changes of state. According to this theory, as we have seen, heat is a species of molecular agitation, which increases with the temperature. In the solid state the molecule oscillates about its mean position. As the temperature rises, the increased knocking of the molecules against one another thrusts them farther apart. The body expands. When a certain temperature is reached, the oscillations become so large that the displacements exceed the elastic limit. The molecules can no longer be held in place. The solid structure disintegrates. The substance flows. It becomes liquid.

To tear a molecule away from its neighbors requires energy, and this is furnished by the heat supplied. The heat that is used up in this way cannot produce any increased thermal agitation, for that would mean to eat your cake and have it too. Hence occurs the considerable amount of heat absorbed without change in temperature, the latent heat, in the case of the crystalline solids, and the excess of heat absorbed during a retarded rise in temperature, in the case of the amorphous bodies. Although this heat apparently disappears, the energy it represents remains in the *potential* form. The molecules have been separated against their mutual attractions. This is like separating stones from the earth. The energy consumed in lifting them can be regained when the stones are allowed to fall upon the earth again. Hence we say that this energy has meanwhile existed in the *potential* form. We could just as well have said that it existed in a *latent* form. And so the heat energy consumed in lifting the molecules can be recovered when, by lowering the temperature, they are allowed to fall together again.

Just as it takes time to demolish a building, so it takes time to disintegrate a solid. And the time required depends upon how fast heat energy is supplied for the work. We might do our demolition job by putting all the workmen on the roof and having them break off pieces one at a time until the entire building is razed. This is how it happens with a crystalline solid. Or we might distribute the workmen all over the building, and set them to prying the stones loose until the whole building collapses. This is how an amorphous body disintegrates. Notice how a pat of butter, as it is warmed, gradually slumps.

In the liquid state, the molecular forces are no longer strong enough to hold the molecules to fixed positions, but only to a

fixed average distance apart. The molecules oscillate about this average distance. As the temperature rises and the thermal agitation increases, the molecules elbow themselves farther and farther apart until at last they are just at the boundaries of their spheres of effective attraction. A little excess of thermal agitation in some part of the liquid will then enable a group of molecules to push their surrounding neighbors quite out of the way, and form a bubble of vapor. This occurring repeatedly and at many places, the liquid boils. Again the energy for pushing the molecules apart is drawn from the heat supplied, and is represented by the latent heat. There is here no distinction between crystalline and amorphous bodies, for all liquids are structureless. All have sharp boiling points, and absorb a large latent heat in boiling.

Finally, in the gaseous state, the molecules released from all effective restraint fly about independently, and push and jostle one another apart indefinitely, or until they are stopped by the walls of a retaining vessel, or in the case of an atmosphere by the gravitational attraction of the planet. As early as 1738, the mathematician Daniel Bernoulli suggested that the indefinite expansion of a gas was thus due to its flying molecules, and not to a repulsive force as Newton had supposed. He was even able to show mathematically that on this assumption a pressure would be produced, by the impacts of the molecules on the walls of a retaining vessel, that obeyed Boyle's law. In 1857 Clausius further showed that if the average kinetic energy of the flying molecules is proportional to the absolute temperature of the gas, Gay-Lussac's law would also be obeyed. These two propositions form the basis of the modern kinetic theory of gases.

At a given moment, of course, the molecules will not all be flying with the same speed. Some will be flying faster, others more slowly than the average. It is the *average* velocity that determines the temperature. Similarly in a liquid or in a solid, the molecular heat agitation will vary from place to place about a mean value. These fluctuations were shown by Maxwell in 1859 to follow the laws of probability. This is the basic theorem of the modern statistical mechanics, which, combined with the quantum theory, is to-day largely displacing the mechanics of Newton, at least so far as atomic and subatomic physics are concerned, and leading to a "Principle of Uncertainty" and other startling things.

VII

EVAPORATION

SOMEWHAT akin to the vaporization of a liquid that takes place at the boiling point, is the slower process of evaporation that occurs at all temperatures. The rate of evaporation increases with the temperature, and depends upon how near the temperature is to the boiling point of the liquid. Hence liquids of low boiling point are more volatile at ordinary temperatures than those of high boiling points. But whereas boiling is a process that involves the whole liquid, evaporation takes place only at the exposed surface, hence increases when the latter is enlarged.

Above the surface of a liquid, there is always a certain amount of its vapor. The presence of this vapor is a hindrance to further evaporation. Its removal promotes the process. Therefore, when a pan of water is set out in a breeze, it dries up faster than when set out where the air is stagnant. If, instead, a liquid is shut up in a bottle tightly corked, so that none of the vapor can escape, then the space above the liquid soon becomes so charged with vapor that it can hold no more. Evaporation then ceases, and the vapor is said to be *saturated*.

Heat is required for evaporation just as it is for boiling. But in this case the heat is drawn from the liquid itself, which is thereby cooled. The faster the evaporation, the greater the cooling. It is therefore greater for the more volatile liquids, such as alcohol, gasoline, or ether, as one may roughly verify by sticking his finger successively in these liquids, and then holding it up to the air.

The cooling produced by evaporation is used in many ways. Nature makes use of it to cool our bodies, by bathing them with perspiration. We promote the process by fanning ourselves, thus driving the vapor away. Similarly we cool our soup by blowing on it—lightly, so that no one will notice. The

Mexicans cool their drinking water by keeping it in porous vessels. The water seeps through to the outside and evaporates. The surgeon uses a very volatile liquid to freeze a portion of the skin that requires a minor operation.

These phenomena of evaporation are readily explained by the kinetic theory. Suppose that a molecule on the surface of a liquid happens to be considerably more agitated than the average. Its super-agitation may become sufficient to enable it to break away from its neighbors, and shoot out of the liquid. Every second, in fact, there will be a certain proportion of the surface molecules that reach this degree of excess agitation, and escape. The proportion increases as the temperature rises. Hence the rate of evaporation increases with the temperature. When the boiling point is reached, the *average* agitation becomes equal to that required for escape, so that the molecules no longer escape only one by one and only from the surface, but in bunches and within the body of the liquid, wherever a slight excess of agitation enables them to push their fellows aside and form a bubble.

Now, since it is only the more lively molecules that can jump out of the liquid, the average kinetic energy of those that remain behind is reduced. Hence the liquid is cooled. And since the escaping molecules carry away more than their fair share of the kinetic energy, the vapor is warmer than the surroundings. But if these livelier molecules hang around, some of them are likely to shoot back into the liquid, and in fact do so. This of course reduces the net rate of evaporation. Hence if the vapor is removed by a breeze, by an air pump, or otherwise, the net rate of evaporation and the cooling of the liquid are increased. In fact, a liquid may be made to freeze itself by this means. If, instead, the liquid is put into a sealed container so that the vapor cannot escape, then, as evaporation proceeds, the vapor becomes continually denser; increasing numbers of molecules shoot back into the liquid until the number shooting back are equal to those shooting out. The liquid is then said to be in *equilibrium* with its vapor. No further change then takes place in the proportion of liquid to vapor, and both assume the same temperature.

At low temperatures evaporation becomes exceedingly slow. Nevertheless it goes on. There will always be now and then a molecule that attains the critical escape velocity, just as in a

sufficiently large group of men there will always be an out-standing individual, no matter how dull the rest. Since in a drop of water, there are at least a billion times a billion molecules, the chances are good that a few will be highly exceptional.

The atmospheres of planets "evaporate" in a very similar fashion. Every now and then in the upper layers, a few molecules acquire a high enough outwardly directed velocity to escape from the gravitational attraction of the planet, and wander off into space. The "escape" velocity for the earth is seven miles per second, for the moon one and one-half, for Mercury two and one-half, for the sun 380 miles per second. It depends upon the size and density of the body. Also, the heavier the gas, the more sluggish its molecules. Hence the earth retains oxygen and nitrogen, but not helium or hydrogen. The moon and Mercury retain no atmospheres at all, whereas the sun and stars retain all the gases including great quantities of helium and hydrogen. But however strong the gravitational attraction and however heavy the gases, *some* evaporation goes on, so that the stars and planets would eventually lose all their atmospheres, if the supplies of gas were not constantly renewed from the body of the planet or star.

How far does the earth's atmosphere extend? That is a difficult question to answer. As we ascend, the air becomes rarer and rarer, so that the question becomes—when is a gas not a gas? When do the molecules become so scattered that they must be considered as individual wanderers, rather than as members of a community?

Meteor trails have been observed at a height of one hundred miles, so that at this height the molecules, few as they may be, are still fairly uniformly distributed. But somewhere above this region we enter another, which is occupied only by molecules that have shot out from the region below, but with insufficient velocity to escape, and which therefore fall back again. This region is full of cascading molecules which shoot out in all directions and fall back again, like the stars of a Roman candle. Still higher we come to a region into which some molecules have shot with a velocity so great that they no longer fall back, but yet the velocity is not sufficient to carry them away entirely. Hence they execute elliptical orbits about the earth, much like comets about the sun. Still beyond we shall encounter here and there a molecule that has shot out with parabolic velocity

or more, and which is leaving the earth forever. One cannot say how high the atmosphere extends, or if it ever really ends.

Even solids evaporate, though usually, of course, with extreme slowness. Nevertheless, in some cases, and particularly near their melting points, the evaporation of solids becomes quite appreciable and important. Thus naphthalene•moth balls, which melt at 176 degrees Fahrenheit, considerably under the boiling point of water, reduce in a few months' time to the size of peas, and eventually disappear altogether. The filaments of tungsten lamps, which run at temperatures as high as 5000 degrees Fahrenheit, while the melting point of tungsten is 5600 degrees, evaporate, and the vapor condenses on the cooler walls of the bulb. This causes the blackening of the bulb. The whole arrangement is virtually a distilling apparatus, which causes the lamp to dim with age, and ultimately to burn out.

Everything, then, evaporates. All liquids and solids, whatever their temperatures, are slowly being converted into vapor. The greater part of the universe is already gaseous. All the stars are gaseous, and enormous masses of gas, as bright or as dark nebulae, are floating about in space. Only on the earth and on other small cold bodies do we find liquids and solids predominating. We live amid exceptional circumstances.

This universal evaporation was once made the basis of an argument, by the astrophysicist Zöllner, that the universe could not possibly have had an infinite past. In that case, he said, everything would have long since already evaporated.

VIII

EFFECTS OF PRESSURE

In the preceding chapters we have spoken of the boiling points of liquids, as though each liquid had but one, and that one were always the same. That is not true. The boiling points vary with the pressure. In order for a bubble of vapor to form in the body of a liquid, it must push back the surrounding liquid that presses in upon it from all sides. This pressure, a short distance below the surface, is substantially the same as that of the atmosphere (or of whatever other gas or vapor may be present) upon the surface of the liquid. If this pressure is increased, a greater expansive force, a greater thermal agitation, a higher temperature, will be required to form a bubble. Increase of pressure, therefore, raises the boiling point, and, conversely, decrease of pressure lowers it. When we speak of *the* boiling point of a liquid, we mean its boiling point at a pressure of one standard atmosphere, which is 14.7 pounds per square inch, and corresponds to a barometer height of 76 centimeters or 29.92 inches.

If we stop up the spout of a kettle and clamp down the lid, the pressure within will rise, and so will the temperature. This is the principle of the steam boiler and of the pressure cooker. By allowing the pressure to increase to a point regulated by the safety valve, the temperature of the water can be raised considerably above its ordinary boiling point. This means a more efficient engine in the one case, and more effective cooking in the other. Conversely, if we attach a hose to the spout, connect it with an air pump, and draw off the vapor, the water will boil at a lower temperature. When one ascends a high mountain, the air pressure diminishes, and boiling takes place at a lower temperature. For this reason it is difficult to make good coffee, or to cook by boiling, unless a pressure cooker is used.

The lowering of the boiling point by reduced pressure can

easily be shown by the simple apparatus of Figure 22. The inverted flask contains water just under 212 degrees Fahrenheit. By squeezing a sponge full of cold water over the flask, some of the vapor within is caused to condense on the glass. This reduces the pressure, and the water immediately boils.

A more satisfactory and complete demonstration, however, can be made with an air pump. By rapidly exhausting the air and vapor above a liquid, the boiling temperature can be lowered any amount we please, even down to the freezing point.
FIG. 22 · BOILING AT REDUCED PRESSURE

This principle is applied in the vacuum pan, used in the manufacture of sugar and in other industries. The juices which have been squeezed out of the sugar cane must be boiled down to remove the greater part of the water. But sugar is very easily burnt. Hence the boiling temperature is lowered by reducing the pressure by means of a pump. One might expect in this way to save some of the fuel required for the boiling, but the working of the pump consumes more than is saved.

A knowledge of the temperatures at which water boils under different pressures is of importance in two great fields—steam engineering and meteorology. Accordingly in 1847 Regnault, at the instance of the French Government, began a long series of accurate measurements covering a large range of pressures. His results, extended by later investigations, are shown graphically

by the curve in Figure 23, which is called the *steam line*. The boiling points of other liquids give similar curves, which we shall also call *steam lines* for short.

On account of the great range of pressures involved, it is impossible to get the whole of this curve within the compass of a single 'conveniently sized diagram, if it is drawn to a uniform scale in the usual way. We have therefore plotted horizontally
FIG. 23—THE REGNAULT STEAM LINE

the cube roots of the temperatures, and, vertically, the fourth roots of the pressures. By this device the diagram is compressed in the region of the higher pressures and temperatures, and stretched out in that of the lower ones. This is desirable because the lower part of the curve is the more important, for pressures above four hundred pounds are seldom used. If the pressures had been plotted to a uniform scale, each pound being represented, say, by the height at which one pound stands on this diagram, the four hundred-pound level would have stood at a height of about thirteen feet, while the rest of the diagram would have extended to over one hundred feet. This, to say

the least, would be very inconvenient. It was not so necessary to compress the temperature scale, but it has been done to prevent undue distortion of the curve, and to make this diagram correspond to that of Figure 36, on page 109, of which it is a part. The real temperatures and pressures, not these roots, have been marked on the scales. Hence they oan be read in the usual way.

From the curve we can read the boiling points corresponding to various pressures. For example, at a pressure of one atmosphere, 14.7 pounds, as read on the vertical scale, we find the boiling point at *B* on the curve to be 212 degrees, which number is read on the bottom scale. Similarly we may find from the curve, that in a steam boiler at 100 pounds pressure, the temperature will be 328 degrees, and at 500 pounds, 467 degrees, etc. We must here remark, that the pressures shown by a steam gauge are pressures above the atmosphere. To get the total or *absolute* pressures, which we here use, that of the atmosphere must be added to the gauge readings. We should also say that for exact work, readings from a curve drawn to a small scale, such as this one, are much too inaccurate. For such work, a *steam table* is used, where all these results and many others useful to engineers are tabulated.

Conversely, we can find from the curve the pressures at which water boils for given temperatures. For example, if we wish to boil water at room temperature, 70 degrees, we shall find that we must reduce the pressure to 0.36 pounds. If we wish to boil it at the freezing point, we must reduce the pressure to 0.089 pounds, corresponding to a barometer height of 0.18 inches, which is a pretty good vacuum.

The highest boiling point given on the curve is 689 degrees, which is attained at a pressure of 2947 pounds per square inch. Here the curve abruptly ends, for the reason that above this temperature water cannot exist in the liquid form, no matter what the pressure is. This is called the *critical temperature*, of which more later.

For a given pressure, the temperature at which water boils is the same as that at which steam condenses. It is therefore indifferent whether we say that the steam line gives the boiling points of water, or the condensing points of steam. They are the same thing. At every point of the curve a *mixture* of both states is present. The water is at the boiling point, the steam

is at the condensing point. If heat is added to the mixture, the water boils. If heat is abstracted, the steam condenses. Hence the two states are in equilibrium, and the steam is saturated. The curve is the *equilibrium line* for a mixture of water and steam. At all points of the diagram to the left and above the curve, the substance is wholly liquid. At all points to the right and below, the substance is wholly vapor or gas. The curve is hence the boundary line between these two states, and wherever we cross it, we pass from the one state to the other.

Hence a vapor in contact with its liquid is always saturated. It is impossible to raise its temperature above the boiling point corresponding to the pressure, for the addition of heat merely causes more water to boil off, and the temperature remains unaltered. Conversely, it is impossible to cool the vapor below this temperature, for the abstraction of heat merely causes the vapor to condense, again at constant temperature. At least this is ordinarily the case. We shall note some exceptions later. But if a vapor is separated from its liquid (drawn into a separate container), its temperature can be raised above the boiling point corresponding to the pressure by any amount we please. The vapor is then said to be *superheated*. This is the condition of the substance *below* the steam line.

If a small amount of liquid is shut up in a sealed container, so that the total volume is kept constant, the liquid, as we have seen, evaporates until the vapor in the space above it becomes saturated; that is, until the pressure of the vapor is that for which, at the prevailing temperature, the vapor is just about to condense. This is also the *pressure* at which the liquid would *boil* at the prevailing temperature. Hence the vapor is at the condensing point, and the liquid is at the boiling point. We are on the steam line. If heat is added to the mixture, its temperature rises, more water evaporates, and the *vapor pressure* rises until it is again at the saturation pressure corresponding to the higher temperature. We are still on the steam line. We have simply moved up a bit. Conversely, if heat is removed, the temperature falls, vapor condenses, and the vapor pressure diminishes until it is again at the saturation value corresponding to the lower temperature. We move down the steam line.

What we have described is a species of boiling and condensing at *constant volume*, whereas these processes are commonly carried out at *constant pressure*. Thus, if we cork up some water

in a bottle at 70 degrees Fahrenheit, the water will evaporate until the vapor pressure reaches 0.36 pounds, and then evaporation stops.   This is the saturation pressure for that temperature —and the liquid is at the boiling point for that pressure.   If we raise the temperature to 100 degrees, the vapor pressure rises to 0.95 pounds; at 212 degrees it reaches one atmosphere or 14.7 pounds; at higher temperatures, it reaches still higher pressures, always as indicated by the steam line at the corresponding temperatures.   We have now virtually a steam boiler, and this in fact is precisely what happens in such a boiler while we are "getting up steam," for this is also a constant volume operation.   The pressure and temperature conjointly rise, keeping always to the steam line, until the opening of the safety valve puts a stop to the pressure rise, and consequently also to the temperature rise, and boiling then proceeds in the usual way at constant pressure and at constant temperature.

If we have the proper proportions of liquid to vapor in a sealed container, we can in this way run all the way up and down the steam line, and even run off the end.   What happens then will be described later.   If there is too little liquid, all of it may boil off at some point, and we then branch off into the vapor region.   If there is too much liquid, all the vapor may condense prematurely, and we then run off into the liquid region.

In the ordinary processes of boiling and condensing, the pressure is *maintained* constant by external circumstances.   The temperature then automatically remains constant, and cannot be altered.   Conversely, if the *temperature* is maintained constant by external means, boiling and condensing then take place at constant pressure, and the pressure cannot be altered. Suppose, for example, that a mixture of liquid and vapor is contained in a cylinder having a movable piston, and that the whole is immersed in a large water bath by which the temperature is kept constant.   We endeavor to compress the vapor by pushing in the piston.   We shall not succeed, at least if we go slowly.   The pressure remains unchanged, the vapor merely condensing.   Ordinarily the compression of a gas heats it.   But in this case the heat of compression is at once absorbed by the water bath, so that the temperature is not changed. What we do in effect is to squeeze the latent heat of the substance out into the surroundings.   Conversely, if we endeavor

to reduce the pressure by withdrawing the piston, we shall not succeed. The liquid at once boils, and keeps the space filled with its vapor at the saturation pressure. In this case we suck up, so to speak, the latent heat required for the boiling from the surroundings.

A form of this experiment can readily be carried out with the apparatus shown in Figure 24. This consists of two barometers a and b, which are prepared in the following way. A glass tube, something over a yard in length and closed at one end, is filled with mercury, and then while the open end is stopped with the finger, the tube is inverted, and this end dipped into a cistern of mercury. The finger is removed, and the mercury in the tube then descends to a height of about thirty inches above the level in the cistern. This represents the atmospheric pressure. In descending, the mercury leaves above it a completely empty space—the Torricellian vacuum. The tube at a is left in this condition. Into the one at b is introduced a small amount of ether. This is done by means of the little syringe with the crooked spout shown at C. The spout is inserted under the open end of the barometer, and some of the contained ether is squeezed out. The ether ascends the tube in bubbles till it reaches the top. The first few drops evaporate immediately, and the pressure of the vapor thus formed depresses the mercury column. The depression increases as more ether is introduced. But at last it stops, and some of the ether remains in liquid form on top of the mercury. More ether then produces no further depression, except by the very light weight of the additional liquid. We have now reached the *maximum* or saturation pressure of the ether vapor. The condition of the apparatus at the end of these operations is shown at A in the figure.

We could have used water for this experiment. But the saturation pressure of water vapor at 70 degrees is only a third of a pound, and this would have depressed the mercury column by only two-thirds of an inch. Ether is much more volatile. Its saturation pressure at 70 degrees is 8.4 pounds, and this depresses the mercury column 17 inches. The effect is conspicuous and surprising.

The mercury cistern has a deep well in the center into which the tube b can be lowered. As we do this, we shall observe that the mercury column does not sink with the tube, but

remains at a fixed height, so that the space above it in the tube diminishes. At the same time the quantity of liquid ether in the tube increases. This stage of affairs is shown at *B*. Some of the vapor has condensed. But the constant height of the mercury column shows that the vapor pressure has remained unchanged. It is still at the saturation value of 8.4 pounds, and still depresses the mercury column by 17 inches. The
FIG. 24—DEEP CISTERN BAROMETER EXPERIMENT

tube must of course be lowered slowly to give time for the latent heat released by the condensation to be dissipated to the surroundings.

If the tube is further lowered, the condensation continues, still without change of pressure, until the ether is completely liquefied. Further lowering of the tube then pushes the mercury down, for the top of the tube is now against a plug of liquid, which is well-nigh incompressible.

By raising the tube, all these operations are reversed. The mercury rises with the tube until the ether begins to boil. From then on it remains at a constant height until all of the ether has vaporized. If it is possible to raise the tube still further without pulling it out of the cistern, the mercury column will again rise, but more slowly now than the tube, showing that as the volume of the now superheated vapor is increased, its pressure diminishes, just as occurs with any gas.

The ordinary process of boiling, as when we put a kettle of water on the stove, is represented on the Regnault diagram (page 66) by the constant pressure line *PBB'*. We start at *P* with the water at 70 degrees, and one atmosphere pressure. As we add heat, the temperature rises, and we move along *PB*, until at *B* we reach 212 degrees and boiling begins. Here, there is a long pause in our progress along the line, for the temperature does not again rise until all the water has boiled off. Then the steam remaining in the kettle is superheated along the line *BB'*, and could have been continued indefinitely. If now we allow the kettle to cool, we retrace our steps. The steam cools along *B'B*. At *B* the saturation temperature is reached, and condensation begins. Again a long pause until this process is completed, and only water is present. The latter then cools along *BP*, until at *P* we are back at the starting point.

We have now less water than before because most of the steam has escaped. But suppose we had heated the water at the bottom of a very tall cylinder provided with a frictionless piston, whose weight was such that it maintained a constant pressure of 14.7 pounds on the contents of the cylinder. The steam resulting from the boiling would then simply push the piston up, and all of it would be saved. The process would then be completely reversible. In this case we must note that the piston and the sides of the cylinder must be non-conductors of heat, for otherwise the steam will condense from loss of heat.

Also the cylinder must be very tall, for the volume of the steam is sixteen hundred times that of the water from which it is derived. If we started with an inch of water on the bottom of the cylinder, the latter would have to be 133 feet high to accommodate the resulting steam. This large expansion and the similar contraction during condensation take place during the pause at *B*. They do not show on the Regnault diagram, because this being a *pt* plot, shows only relations of pressure and temperature. To show also the volume changes would require another dimension.

A liquid, we have seen, can also be brought to boil without changing its temperature, by simply reducing the pressure, as by means of a vacuum pump. Since the function of the pump is merely to enlarge the volume, we may imagine this process also carried out in a very tall cylinder provided with a piston which we gradually raise. We thus produce the required enlargement of volume by a single long stroke, instead of by a succession of short ones as with the pump. The process is essentially the same as that of our deep cistern barometer. Let us start again with water at 70 degrees, and the piston pressing directly upon it with a pressure of 14.7 pounds per square inch. As we raise the piston the pressure diminishes, and we must now suppose the cylinder such a good conductor of heat, that the prompt inflow of heat from the surroundings keeps the temperature constant. We thus descend the constant temperature line *PAA'* on the Regnault diagram. At *A* we reach the boiling *pressure* corresponding to 70 degrees. Here there is a *very* long pause in the descent, for although the piston is being continually withdrawn, the liquid is vaporizing, and the pressure does not drop. The increase in volume at this temperature is much greater than at 212 degrees. It is no less than fifty-four thousand times. Hence, if we start with an inch of water, we shall require a tube forty-five hundred feet high to accommodate the vapor. This tremendous volume is due to the low pressure, 0.36 pounds. When at last the liquid is completely vaporized, further withdrawal of the piston reduces the pressure, and we continue the descent along *AA'*. Despite the moderate temperature, the steam is now superheated, for at *A'* the pressure is 0.089 pounds, which corresponds to a boiling point of 32 degrees. The steam at 70 degrees is therefore above the vaporization temperature corresponding to its pressure, and

so by our definition above is superheated. Superheated steam is therefore not necessarily excessively hot, as its name would suggest, although the kind that the engineer deals with usually is. But the meteorologist often has to do with superheated steam that is extremely cold, that is even below the freezing point.

We can now reverse our whole experiment by pushing the piston in, condensing the vapor, and eventually returning to the starting point. During the expansion process, heat had to be absorbed from the surroundings to keep up the temperature, and to provide the latent heat of vaporization. During the contraction, heat had to be rejected to the surroundings to keep the temperature down, and to remove the latent heat.

The freezing points are also affected by pressure, though to a far less extent than the boiling points. Also we find opposite effects depending upon whether the substance expands or contracts on solidifying. If it expands, pressure will hinder the process; if it contracts, pressure will aid it. Hence we may reasonably expect that when the pressure is increased, bodies that expand will require a greater cold, those that contract, a lesser cold, to solidify them. These are indeed the facts. Increase of pressure lowers the freezing point of a substance like water which expands, and raises that of one like paraffin which contracts on solidifying. The effect, however, is extremely small. An increase in pressure of one atmosphere lowers the freezing point of water only 0.013 Fahrenheit degrees, and raises that of paraffin 0.036 degrees. The effect is very nearly proportional to the pressure, so that at seventy-eight atmospheres, or 1170 pounds per square inch, the freezing point of water is lowered one degree. The effect depends also upon the magnitude to the volume change on solidification, so that for nearly all other substances it is smaller than for water or paraffin.

It was at one time thought that the force of expansion when water froze was irresistible. The idea seems to have been that if the temperature is below freezing the water simply *must* freeze, *must* expand, and therefore *must* overcome any resistance that opposed it. Indeed, very powerful effects can be produced. Great weights can be lifted by the expansion of water on freezing. Huygens succeeded in bursting a cannon by freezing water contained in it. But there are no irresistible forces in

nature. This giant though strong is not of unlimited strength. If the temperature is 31 degrees Fahrenheit, a part of the water in a confined space will freeze until the expansion has produced a pressure of 1170 pounds. If the container is strong enough to withstand that, the rest of the water simply will not freeze, and there will be no bursting. If the temperature is 30 degrees, the freezing will stop at 2340 pounds, and so on. At each temperature there is a definite limit to the expansive force. Besides, modern investigation has shown that at −8 degrees Fahrenheit, at which a pressure of 31,500 pounds per square inch is reached, the freezing point ceases to be lowered by increased pressure. Thereafter it rises, and the water, instead of expanding, contracts on freezing, as will be more fully explained in the next chapter. 31,500 pounds is hence the utmost pressure that can be obtained by freezing water in a confined space. Containers have been made that can withstand that pressure and a good deal more, so the frost giant has been successfully chained.

The lowering of the freezing point by pressure means that ice can be melted by pressure. When the pressure is relieved, the water freezes again. This phenomenon is called *regelation*. It has many important consequences.

Every skater knows that when the weather is very cold, and the ice is consequently dry, the skating is not good. The ice does not seem to be even slippery. In fact dry ice is not especially slippery. It is the film of water on wet ice, which, acting as a lubricant, makes it slippery. Now, as Joly pointed out in 1899, the pressure under a skate is very great. On account of the curve of the blade and the hollow grinding, the area on which a skate rests is very small, one-fiftieth of a square inch or thereabouts. With a skater weighing one hundred and forty pounds, a pressure of seven thousand pounds per square inch is produced. This is sufficient to depress the freezing point 6.2 degrees, so that if the temperature of the ice is not under 26 degrees Fahrenheit, it will be melted by this pressure. The skater therefore glides along on a film of water, which, if the temperature is below 32 degrees, recongeals after he has passed.

It is this regelation that enables a glacier to descend a sinuous valley. Wherever an obstruction is met, a great pressure is produced, which melts the ice. But the water passes around the obstruction and freezes on the other side of it, where the

pressure is relieved. Hence it appears as though the ice itself had bent around or over the obstacle like a flexible thing. The process can be strikingly demonstrated in the following way. A block of ice is supported between two tables, and a loop of thin copper wire is passed around the middle of the block, and a rather heavy weight is attached to it. The pressure of the wire melts the ice immediately beneath it, but the resulting water passes around to the top of the wire, and refreezes. Consequently the wire gradually eats its way through the ice, and will eventually pass completely through it and the weight fall to the floor. But the block of ice remains undivided and as solid as ever. By pressing two pieces of ice together they can be made to freeze together, and, as every one knows, the glacier itself is formed by the compacting of great masses of snow in the upper part of the valley.

IX

THE TRIPLE POINT AND
HIGH PRESSURES

SINCE decrease in pressure raises the freezing point and lowers the boiling point of water, at some reduced pressure the two should meet. This meeting can in fact be brought about by the following experiment devised by Leslie. A small dish of water and a large dish of strong sulphuric acid are placed under the receiver of an air pump. The air is rapidly exhausted, and the water vapor is largely absorbed by the sulphuric acid, which has a strong affinity for it. The rapid evaporation lowers the temperature of the water faster than the boiling point descends, so that the water does not boil until the rising freezing point is met. Then it *boils and freezes at the same time*. Bubbles of steam rise from the interior of the liquid—very cold steam, for they freeze immediately on reaching the surface. The process continues until the whole is a solid block of ice, which can then be removed from the receiver. Since the utmost that the pressure can be reduced is from one atmosphere to zero pressure, and this we have seen would raise the freezing point only to 32.013 degrees Fahrenheit, it is obvious that the meeting point must lie between this temperature and 32 degrees. It lies, in fact, at 32.01289 degrees, and at a pressure of 0.089 pounds per square inch. The ice is hence about as cold as that produced in the ordinary way.

This experiment can also be carried out with a substance whose freezing point is lowered by diminished pressure, because the descent of the freezing point is so much slower than that of the boiling point, that the latter soon overtakes it.

This point where a substance boils and freezes at the same time is called the *triple point*, because solid, liquid, and vapor there exist together. This point for water is the beginning of

the Regnault steam line of Figure 23, and represents the lowest pressure at which water can exist. If we plot the pressures and corresponding temperatures at which water freezes, we get another line on this diagram, the *ice line*, which also starts at the triple point, as shown in Figure 25. This line leans to the left, in the direction of decreasing temperature, because increase of pressure lowers the freezing point. For a substance which contracts on solidifying, this line leans to the right, as shown in Figure 34, Chapter XI. The steam line, it will be remembered, divides the Regnault diagram into a liquid and a vapor region. The ice line further subdivides the upper part of the diagram into a liquid and a solid region, and the line represents a *mixture* of liquid and solid in equilibrium.
FIG. 25—THE TRIPLE POINT

Yet a third line starts at the triple point. This divides the solid from the vapor region. It is called the *hoar frost* line. In crossing this line, the vapor transforms directly into the solid (the process of sublimation) or the solid into the vapor. This can only occur at pressures and temperatures below those of the triple point, as along the constant pressure line *CBA* in the figure. At *B* direct vaporization of the solid occurs if heat is added, and sublimation, if heat is abstracted. On the line there is always a mixture of solid and vapor in equilibrium. The same sort of diagram applies to substances other than water, but we shall retain the names ice and frost lines for short.

In winter when the air in the house is dry, which means that

the pressure of the water vapor contained in it is very low, and the windowpanes are below 32 degrees, this vapor deposits on the panes directly as frost. It does not condense first to water and then freeze. In that case clear ice would be produced. The beautiful frost patterns result only from the direct deposition of the vapor in solid form. Similarly, snowflakes are crystallized vapor, whereas hailstones are simply frozen raindrops.

The direct passage of ice to vapor and the reverse are of rather rare occurrence, because the triple point of the substance is so low. But for many substances this point lies much higher, so that the phenomena occur at ordinary pressures and temperatures, and even much above. Sulphur and iodine are examples. Frozen carbon dioxide melts directly to vapor, for which reason it is popularly called dry ice. The steam we see rising from it is not its vapor, but is the water vapor of the air, which has been condensed by the cold but invisible carbon dioxide vapor. If the dry ice is placed in a pan of water, this apparent steaming is much increased.

If the triple point pressure of a substance is above one atmosphere, the substance can exist in the liquid form only under increased pressure, and this no matter how much the temperature is lowered. This is the reason why we never see iodine, carbon dioxide, or other such substances in the liquid form, except perhaps in a glass vessel under pressure.

The most remarkable substance in this regard, however, is carbon. In the electric arc it vaporizes directly. In the bright parts of flames its vapor precipitates at once into solid particles, as is evidenced by the fact that they will deposit on a colder body as soot. No one has ever seen carbon in the liquid state. Evidently both the pressure and the temperature of its triple point are extremely high. We must imagine tp in Figure 25 shifted a long way upward and to the right, so that nearly all of the diagram is solid and vapor, and only a little upper corner is liquid. If diamonds are crystallized from liquid carbon, that would account for their rarity. Moissan, proceeding on this theory, cooled white-hot iron containing small specks of carbon very suddenly. The contraction of the iron produced a great pressure on these particles, and he obtained in this way microscopic diamonds. We can produce in our laboratories very high temperatures, or very high pressures, but not both

together.   As yet, nature alone can do this, in the depths of the planets and stars.

We have mentioned that solids show minor changes of state having all the characteristics of those major changes from solid to liquid and liquid to gas, the chief of which is a change in volume at constant temperature and pressure, accompanied by the absorption or rejection of a latent heat.   In the year 1900, Tamman[1] carried out a remarkable series of experiments, the primary objects of which were to determine whether the depression of the freezing point of water continued indefinitely
FIG. 26—TAMMAN'S ALPHA ICE

as the pressure increased, and whether the rate was constant. For this purpose he carried the pressure up to the hitherto unheard-of value of 3500 atmospheres, or 52,000 pounds per square inch.   He found that the rate of depression increased as the pressure rose, so that the ice line of Figure 25 *curves* to the left.   But at −8 degrees Fahrenheit and 2200 atmospheres, an abrupt and remarkable change took place.   The ice suddenly contracted by about 20 per cent so that its volume was now *less* than that of water, and with further increase in pressure, the melting point now rose, as we have mentioned in the previous chapter.   From this point on, the ice line leans to the right, as shown in Figure 26, which is Tamman's diagram.   In short, a change of state had taken place.   A new form of the solid had appeared.   Tamman called it alpha ice.   It is obvious also

[1] Tamman, *Annalen der Physik*, Vol. II, p. 5.

that the point on the ice line where this change took place is a new triple point, for here the old and the new ice and water all three meet. Tamman, indeed, was able to follow the equilibrium line that separates the two forms of ice for a short distance, as shown at T_1A in the figure. The ordinary ice line T_0T_1 leans so much more to the left in this diagram than in Figure 25, because of the small scale on which the pressures are plotted. The ordinary triple point T_0 on this scale is practically at zero pressure.

In these experiments, the ice or water was compressed in a strong steel cylinder, and so of course could not be seen. Only the sudden change in volume at constant temperature and pressure announced a change of state. But Tamman was anxious to get a look at the new ice if possible. So he cooled it, still at high pressure, to the temperature of liquid air, released the pressure, and got it out of the cylinder. It looked just like any other ice, but was extremely cold and dry. As it warmed up, it gradually melted into ordinary ice, with a large increase in volume.

In later experiments Tamman discovered a third kind of ice, and thought he had found indications of a fourth, but the latter has not been confirmed.

In 1911 P. W. Bridgman[2] of Harvard University, having invented a new kind of packing, was able to carry the pressure up to 40,000 atmospheres or 600,000 pounds per square inch, nearly twelve times as far as Tamman. This is the pressure that would be produced by a pile of bricks 100 miles high, or that would be found 80 miles beneath the surface of the earth. At these stupendous pressures some profound changes occur in the properties of matter. Bridgman found that steel became plastic and could be made to flow like pitch. Soft rubber, instead, became hard and brittle like glass. The rubber washer would crack and the softened steel flow into the cracks.

With this apparatus Bridgman extended Tamman's experiments, discovering five different kinds of ice, which he numbered I, II, III, V, and VI. Number IV was reserved for Tamman's fourth variety, but this was not found. Number I is ordinary ice, III is Tamman's alpha ice. Of 11 possible transition lines, 10 were found; of 6 triple points, 5 were found. All of these forms of ice except Number I are of less volume than

2 Bridgman, *Proc. Amer. Acad. Arts and Sciences*, Vol. 47, p. 441.

water.   Figure 27 is Bridgman's diagram.   The temperatures
are given in centigrade degrees.   On the Fahrenheit scale the
range is from −112 to 176 degrees.   The pressures are in
kilograms per square centimeter, or what are called metric
atmospheres, which are ninety-seven hundredths of ordinary
atmospheres, hence practically the same.   Ice Number VI
seems to be the final form.   No further change was found at
the highest pressures and temperatures used.   And in this form
the freezing point rises continually with the temperature.
FIG. 27—BRIDGMAN'S FIVE FORMS OF ICE

At the time of the gold rush to the Klondike, many were the
tales told of the cold encountered.   Perhaps one of the tallest
was that told by a man who said that one day he set a bucket of

hot water out on his porch to cool, and the water froze so
quickly that the ice was still hot.   While this may be an exag-
geration, Bridgman's ice Number VI at 160 degrees Fahren-
heit is distinctly hot ice.   But we can only have it at 300,000
pounds pressure, so that we shall probably never have a chance
to burn our hands on it.   If we could only produce pressure
enough, it appears that we could have ice at any temperature
we please, even above the ordinary boiling point of water.

Bridgman also experimented with frozen mercury and with
many other substances at these extraordinarily high pressures.
He found that many of them exhibited similar changes of state
within the solid state.

X

SOLUTIONS

IT had long been known that the boiling point of a liquid is raised when a substance is dissolved in it. But in 1822, Faraday, while measuring the boiling points of various aqueous solutions, made the curious discovery that when he lifted his thermometer so that the bulb was in the steam just above the boiling fluid, it always dropped to 212 degrees Fahrenheit. Hence it appeared that, however elevated the boiling point of the solution might be, the steam remained at 212 degrees, the boiling point of the pure solvent.

Gay-Lussac, on hearing this, objected that the temperature of the steam could not possibly be appreciably lower than that of the liquid from which it had just been disengaged, and concluded that either Faraday's thermometer was wrong, or that he had not observed with sufficient care.

But Faraday's observations and his thermometer were correct. The latter does read, and rightly reads, 212 degrees in the steam. Yet Gay-Lussac's objection was entirely justified. This is not the temperature of the steam. Now, how can a thermometer be right if it registers the wrong temperature? The answer is that the bulb is wet, and the water that has condensed upon it is pure water—it is distilled water, for the solids remain behind when a solution is boiled. If the thermometer falls below 212 degrees, water condenses upon it and, giving up its latent heat, warms the thermometer. If it rises above 212 degrees, this water boils off, and being pure water it boils at 212 degrees and, by abstracting its latent heat from the thermometer, cools the latter. When we put a kettle of water on the stove to boil, we surround it by flames that may be a thousand degrees hotter than the water. Yet we cannot raise the temperature of the water above 212 degrees. And so the hot steam surrounding the thermometer is powerless to raise its

temperature above the boiling point of the pure water that covers it. Wet the bulb of a thermometer exposed to the air. Its temperature immediately drops, because of the evaporation of the water. And if the supply of water is kept up, by means of a wick or otherwise, the temperature will continue to fall until it approaches the *dew point*. This is nothing other•than the boiling point of water corresponding to the pressure of the aqueous vapor in the air. In fact, the humidity of the air can be measured in this way, as will be more fully explained in Chapter XIII. On the other hand, when radiation falls upon a thermometer, it registers a higher temperature than that of the surroundings, as will be explained in Chapter XV. A perfectly correct thermometer therefore does not always register the temperature of its surroundings, and special precautions have sometimes to be taken to insure that it shall do so.

Three and a half decades after Faraday's work, the chemist Wüllner made numerous measurements of the boiling points of solutions. He found in general that the boiling point was raised in proportion to the concentration of the dissolved substance. But there were many exceptions, many substances behaving quite erratically and incomprehensibly. The presence of a dissolved substance also *lowers* the freezing point, and by a considerably greater amount than it raises the boiling point. Here, too, the effect was generally in proportion to the concentration, but there were many exceptions.

This whole subject remained in the greatest confusion until Raoult in 1883 found that *organic* substances behaved quite regularly. For nearly all of these, the freezing point depressions were strictly proportional to the concentrations. Furthermore, he found that if we take of each of these substances a number of grams equal to its molecular weight—what is called a *gram-molecule*—and dissolve it in one hundred grams of water, then all of these solutions show the *same* freezing point depression, about 33 Fahrenheit degrees. But all gram-molecules contain the same number of molecules. Hence we may say that the freezing point depression per dissolved molecule is the same for all organic substances dissolved in water, or the depression is proportional to the molecular concentration. This is called Raoult's law, and the depression produced by a gram-molecule is called the *molecular depression*. He found the same

law to hold for other solvents, but each gives a different molecular depression.

There were still some exceptions to this rule, but Raoult found that they all could be laid to two causes. The first of these is *hydration*, the chemical union of each molecule of the substance with one or more molecules of the solvent, which, by depleting the solvent, has the effect of increasing the concentration. The second is *polymerization*, the combining of the molecules of the substance with each other into groups of two or more. Since each group acts as a single unit, this has the effect of reducing the concentration. What counts, therefore, is the number of independent parts into which the dissolved substance is divided, in proportion to the number of free parts of the solvent present.

In 1888, Raoult made a similar investigation with regard to the boiling points, and, so long as he confined himself to organic substances, found a similar rule to apply. If a gram-molecule of each of these is dissolved in one hundred grams of water, each produces the same boiling point elevation, about 9 degrees Fahrenheit. This is the *molecular elevation* for water. Other solvents give other elevations. The few exceptions were again found to be due to hydration and polymerization.

The two phenomena are really one. What a dissolved substance actually does, Raoult showed, is to lower the vapor pressure of the liquid, and he was able to sum up all his results in a single statement, as follows: If any organic substance is dissolved in any solvent, in the proportion of one molecule of the former to one hundred molecules of the latter, the vapor pressure of the liquid is lowered by one per cent. This occurs not only at the boiling point, but at every other temperature. In short, the whole steam line is lowered, as shown in Figure 28. The full line is the steam line for water; the dotted line is that for a 20 per cent solution of sugar in water, which is about in the proportion of one molecule of sugar to one hundred molecules of water. The figure is not drawn to scale, and the depression of the steam line is much exaggerated.

Now water boils at 212 degrees because at that temperature the vapor pressure within the liquid reaches the value of one atmosphere, and is then equal to the external pressure. Under these circumstances a bubble of steam can form in the liquid. When a substance is dissolved in the water, the vapor pressure

of the liquid is lowered, and at 212 degrees is less than one atmosphere. Hence the temperature of the solution must be raised until its vapor pressure reaches this value. Thus in the figure, *B* is the boiling point of water at 212 degrees and one atmosphere. In order to boil the solution, its temperature must be raised until its steam line intersects the constant pressure line *PB* at *B'*, an elevation in this case of three-tenth degrees. Similarly a solid melts when its vapor pressure becomes equal to that of the liquid, in short, when the frost and steam lines
FIG. 28—STEAM LINES OF SOLVENT AND SOLUTION

intersect. This occurs at *F* for the liquid, but at *F'* for the solution, or one degree lower in this case. From the figure one can see also that the considerable lowering of the freezing point is due to the fact that the slopes of the frost and steam lines differ but little.

But why is the vapor pressure of a liquid diminished by a dissolved substance? The answer to this question has come to us by a most curious and circuitous route. Every time we drop a spoonful of sugar into a cup of coffee, a marvelous thing happens, but it is so commonplace that it excites no wonder. The sugar, of course, sinks to the bottom because it is heavier than the liquid. But it does not stay there. In a little while, even if we do not stir the coffee, we find that some of the sugar has risen to the top, for by sipping a little coffee from the surface we find that it is sweet. After a longer time, we shall find that the whole cupful is uniformly sweet. The sugar has distributed itself uniformly throughout the liquid. And it will remain so distributed no matter how long the solution stands. If we pour a spoonful of sand into the coffee, it too sinks to the bottom. But it *stays* there. If we pour in a spoonful of oil, it rises to the top, for it is lighter. And it stays there. Neither of these

substances will diffuse throughout the liquid.   Why, then, does
sugar do so, and how can it raise itself against the force of
gravity?   Why does sugar and not sand possess this ability?
It explains nothing to say that the one is soluble while the other
is not, for by solubility we mean the very power we are speaking
of.   We do not solve a problem by giving it a name.

Let us examine the facts a little more closely.   In the year
1819 Gay-Lussac had a dispute with some of his colleagues, who
contended that if a solution were allowed to stand long enough
the dissolved substance would finally settle down, and the
solution become more concentrated at the bottom.   To test this
assertion, Gay-Lussac filled several tubes over six feet in length
with different solutions, and having sealed them hermetically
to prevent evaporation, set them in an upright position and
allowed them to stand for *six months*.   At the end of that time
he took samples from the top and bottom of each tube, and, by
the most accurate analyses of which he was capable could find
no difference in the concentrations at the top and bottom of any
tube.   Hence the diffusion is both uniform and lasting.   Ac-
cording to modern theory, however, the concentration at the
bottom should be slightly greater than at the top, but it would
take a much longer tube to show it.   At a depth of 300 feet, a
10 per cent solution of common salt should have a concentration
one twentieth of one per cent greater than at the top.   The
reason for this will appear presently.

The slow diffusion of a dissolved substance throughout a
liquid can be observed by dropping a crystal of some highly
colored substance into a bowl of quiescent and preferably hot
water.   Permanganate of potash, obtainable at any drug store,
is excellent for this purpose, because it is highly soluble and has
an intense purple color.   Take one of the tiny crystals and let it
slide down the side of the bowl into the water.   As soon as it
touches the water it begins to dissolve and, as it slides toward
the center of the bowl, it leaves behind a trail of what looks like
purple smoke.   In fact, it looks for all the world like a miniature
destroyer laying down a smoke screen.   This is a concentrated
solution, which being heavier than water slides slowly down
toward the center of the bowl.   Meanwhile the little crystal at
the bottom continues furiously to belch forth fumes until it is
completely dissolved.   These fumes form a little pool at the
bottom of the bowl.   For a few minutes it looks as though all

were over. But if we continue to watch, we shall presently see that the surface of the purple pool is slowly rising. It becomes arched, its color less intense, its outlines less distinct. Soon it becomes nearly globular in form. Hazy and cloudlike, it slowly expands until it fills the whole liquid, and the purple tinge is uniform throughout.

Suppose we wished to stop this expanding cloud. A sure way would be to stretch an impenetrable barrier across the liquid. When the cloud reached this, it would of course stop, just as it did when it reached the sides of the vessel and the surface of the liquid. But suppose we stretch what is called a *semipermeable* membrane, that is, one which stops the dissolved substance, but allows the liquid to pass freely. Then a curious thing happens. The liquid seeps through the membrane into the solution below, as though it has a strong attraction for it. This causes the solution to expand and press up against the
FIG. 29 OSMOTIC PISTON

membrane with a considerable force. This pressure, which can be measured, is called the *osmotic pressure*.

Suppose we stretch the membrane across the bottom of a piston pierced by many holes, and fit the piston in a cylinder, as shown in Figure 29, with the solution below and the pure

solvent above. The expanding cloud of the dissolved substance will slowly push the piston right up to the top of the liquid. And if we elongate the cylinder and add more liquid, the piston will be pushed up to the top of that, and so on indefinitely. Of course you can prevent the piston from rising by pushing down on it. But you will have to push surprisingly hard to stop this fluffy cloud. A 30 per cent solution of sugar in water will exert an osmotic pressure of 20 atmospheres or 300 pounds to the square inch. You might as well try to stop the piston of a locomotive. And there are solutions which give osmotic pressures as high as four or five thousand pounds. It is no wonder, then, that a substance in going into solution can lift itself against gravity, when it can lift in addition loads so much greater than its own weight.

Curiously enough, the first extensive and accurate measurements of osmotic pressure were made by a botanist, Pfeffer, in 1877. This happened because the matter has much to do with the exchange of liquids between the living cell and its environment. Pfeffer's work was naturally confined mostly to organic substances. For these he found that the osmotic pressure was proportional to the concentration and to the temperature.

As the piston rises in Figure 29, the solution dilutes itself, and the pressure diminishes. When the piston has risen to the double height, the volume of the solution is doubled and its concentration is reduced to one half. According to Pfeffer the osmotic pressure is then also reduced to one half. Hence the pressure varies inversely as the volume of the solution. If the concentration, that is the volume, is kept constant, the pressure varies directly as the temperature. Is there not something familiar about these two statements? Of course there is. They are nothing other than Boyle's and Gay-Lussac's laws for perfect gases. Osmotic pressure therefore obeys the same laws that gas pressure does.

Indeed, there is much similarity between the process of dissolving and that of fusing. Only, instead of the molecules flying apart from excess of heat agitation, they seem to be pried apart by the penetration of the liquid into the solid. This is heavy work, and demands energy. A latent heat is therefore required, just as for fusion, only in this case it is drawn from the liquid, which is thereby cooled. Thus, if sodium sulphate is dissolved in water that is already tolerably cold, a drop in

temperature to 5 degrees Fahrenheit can be produced. The molecules of the solid, once freed from one another's grasp, fly about after the fashion of gas molecules, but are hampered in their movements by the surrounding molecules of the liquid. Nevertheless, they gradually bump their way through these, and eventually fill completely and uniformly any volume of solvent that is offered to them, just as a gas expands and fills any available volume of space. The only difference is that a substance diffuses slowly, whereas a gas expands rapidly. But the effect in the end is the same.

This analogy between a dissolved substance and a gas was first pointed out by Van't Hoff in 1887, and was pursued further by him. If we take a gram-molecule of various organic substances, he showed, and dissolve each in the same quantity of water, then each of these solutions will, at the same temperature, show the same osmotic pressure. But all of these solutions contain the same number of molecules. Here we have a perfect analogue of Avogadro's fundamental gas law, which states that equal volumes of all gases at the same temperature and pressure contain the same number of molecules. Furthermore, this analogy holds not only qualitatively but quantitatively. A given number of dissolved molecules in a given volume of solvent at a given temperature, will exert the *same* pressure as an equal number of gas molecules in an equal volume and at the same temperature. In short, if from a solution which completely fills a closed container we could remove all the molecules of the liquid, and leave those of the dissolved substance in place, the pressure exerted by the latter would remain unchanged. But in place of a solution, we would then have a gas.

We have so far compared the behavior of a dissolved substance with that of a *perfect* gas. The perfect gas laws are closely obeyed, however, only when the solutions are very *dilute*. But this need not surprise us, since gases themselves do not follow these laws very closely unless they are sufficiently attenuated. Now solutions are ordinarily much more concentrated than gases. A thirty per cent sugar solution, for example, contains in a given volume twenty times as many sugar molecules as the same volume of air contains of gas molecules at the same temperature. It is for this reason that the sugar solution exerts twenty times the pressure that the air does, or twenty atmospheres. Nevertheless, it is useful to set up the fiction and study

the behavior of an "ideal solution," just as we did that of a "perfect gas," and express the behavior of actual solutions by their departures from it.

We can now see why the concentration of a solution at the bottom of a tall tube is slightly greater than at the top. We have only to suppose the liquid molecules removed and we have then simply a column of gas. The layers of gas at the bottom will be slightly compressed by the weight of those above, and will be denser, just as the atmosphere is denser near the earth. Indeed, the increase in concentration of a solution with the depth can be calculated from the same formula used for the air.

We can now at last see why the vapor pressure of a liquid is lowered by a dissolved substance. Let us pour a quantity of some solution into a thistle tube, close the mouth with a semipermeable membrane, invert the tube and dip it into a vessel containing pure solvent, say, water, as shown in Figure 30.
FIG. 30—OSMOTIC AND VAPOR PRESSURE

Water then penetrates the membrane and passes through into the solution. The volume of the latter is thereby increased, and it rises in the stem of the tube. This goes on until the weight of the column balances the effort of the water to get in. The height of the column then measures the osmotic pressure.

Suppose, now, we cover the whole apparatus with a bell glass

jar hermetically sealed as shown. The space within soon becomes filled with saturated water vapor. This vapor is in equilibrium both with the water in the vessel, and with the solution at the top of the column, for evaporation has ceased at both places. Now the pressure of the vapor at the top of the column is less than it is at the level of the water by the weight of a column of vapor equal to the height of the solution column, h in the diagram. Hence the vapor pressure of the solution must be reduced by a like amount, for otherwise evaporation would occur at the top of the column, and it does not. Knowing h, we can calculate the amount of this reduction. Hence, from the osmotic pressure of a solution, its vapor pressure at any given temperature, and consequently its boiling and freezing points, can be calculated. It follows that all solutions having the same osmotic pressure have also the same boiling and freezing points—*isotonic* solutions they are called. Such solutions when separated by a permeable wall do not interpenetrate. Thus the surgeon uses a solution that is isotonic with the blood serum to wash a wound, for it does not penetrate the tissues and dilute the blood, nor draw the blood out and increase the bleeding.

But all these beautiful theories of Raoult and Van't Hoff applied only to *organic* substances. All the common *inorganic* substances, which comprise by far the greater part of our material world, refused to obey them. They gave osmotic pressures, boiling and freezing point changes, that were too large—that corresponded to more molecules than were actually present. Sometimes they gave values that were twice too large, as though each molecule had been split in two. This was a very serious difficulty which threatened the whole theory. The manner in which it was finally overcome is also curious and roundabout.

As early as 1878, a young student, Svante Arrhenius, at the University of Upsala in Sweden, had conceived a new theory as to the way in which a current of electricity is conducted through a solution. Shortly afterwards he offered a dissertation on the subject as candidate for the doctor's degree. This dissertation involved both physics and chemistry, but the science of physical chemistry was yet unborn—at least no one then knew that this paper was its birth certificate. There was a Department of Physics and a Department of Chemistry, but neither wished to

father the hybrid child.   The chemists particularly objected to the proposal of this young candidate, that when a substance like sodium chloride (common salt) was dissolved in water, the molecule NaCl, one of the tightest combinations of two elements known and requiring a great deal of energy to separate them, split in two, and formed a sodium and a chlorine *ion*, the one positively and the other negatively electrified.   Now sodium and chlorine are also among the most active elements known.   Sodium has a strong affinity for water, and unites with it with flame and fury, while chlorine is a pungent, poisonous yellow gas.   How could the mere addition of electrical charges tame these furious elements, and make them to lie down peacefully together in a beaker of water?   But the physicists saw that this theory accounted very handily for the conduction of electricity through a solution.   The two sets of charged ions move, by virtue of electrostatic attractions, in opposite directions, and transport the electricity from pole to pole.   Many obscure details of electrolytic conduction also became plain.

Arrhenius got his degree, but a full account of his *dissociation theory* was not published until 1888.   Meanwhile he had worked with Van't Hoff and shown him how the splitting of the molecules accounted for the abnormally high osmotic pressures of inorganic solutions, for these are all conductors of electricity, whereas organic solutions are nonconductors.   The dissociation, however, is not always complete.   When a solution is very concentrated, only a few molecules split.   As the solution is increasingly diluted, more and more of them split.   But the degree of dissociation, Arrhenius showed, can always be determined by measuring the electrical conductivity of the solution, and when in this way are counted all the independent parts, molecules, groups, and ions, into which the substance is divided, it obeys the laws of Raoult and Van't Hoff perfectly.

It is perhaps needless to add that the dissociation theory of Arrhenius did much more than solve this one problem.   It gave birth to the new science of physical chemistry; it was the beginning of the new electrical theory of matter; it gave a new conception of chemical affinity; and it was, so to speak, the entering wedge that finally split the atom itself into protons and electrons.   The revolution it effected in chemistry was

only the forerunner of the still greater revolution that followed in physics.

Avogadro's law enables the chemist to determine the molecular weight of any gas from its density, for the one is proportional to the other. Van't Hoff's extension of the law to solutions enables the chemist to determine the molecular weight of any substance that can be dissolved in any solvent. For this purpose he measures either the boiling point elevation or the freezing point depression, preferably the latter, because it is larger. The method is extremely useful, especially in the case of organic substances with their huge and complicated molecules, containing sometimes a thousand or more atoms. So if the physicist has rudely upset the chemist's ideas with his dissociation theory, he has in return provided him with a powerful weapon for knocking his molecules to pieces, and counting the number of atoms they contain.

The depression of the freezing point of water by dissolved substances is the basis of many freezing mixtures, such as that of ice and salt used in making ice cream. The salt dissolving into the ice lowers its melting point, thus causing some of it to melt. But this requires that the latent heat of fusion be supplied, and this must be drawn from the mixture itself and its surroundings. And so the melting and cooling proceed hand in hand, until with a proper proportion of the ingredients a temperature of o degree Fahrenheit can be attained. Curiously enough, the amount of heat in the mixture remains unchanged, except for what is absorbed from the surroundings. A part of it merely passes from the temperature-producing kind into the latent form, with a consequent reduction in temperature.

There are other and more powerful freezing mixtures. One part of calcium chloride to four of shaved ice will produce a temperature of -65 degrees Fahrenheit.

When a dilute solution is cooled to its freezing point, pure ice forms at first, just as pure steam is boiled off from a solution. Thus, the ice formed on the ocean is not salt. As more and more ice separates out, the remaining solution becomes more and more concentrated, and the freezing point descends until the solution has become saturated. Then, and then only, the solution itself freezes. Salt ice can be produced in this way only at a temperature of -8.6 degrees Fahrenheit.

XI

Real Gases

THE reader who had a tough time in Chapter III, because of too many dimensions and other complications, will have a worse time in this one. We there merely mentioned the fact that there were complications, that real gases did not conform entirely to the patterns of perfect behavior laid down by Boyle and Gay-Lussac. We now propose to set forth what some of those complications are. We do this, not from any desire to be annoying, but because some of the most remarkable discoveries have resulted from the study of the bad behavior of gases and from the endeavor to find out just why they behaved badly. We wish to tell about these discoveries.

We pointed out in Chapter III how preposterous it was to suppose that any self-respecting gas would suffer itself to be crushed out of existence by any excess of pressure whatsoever, as according to the rule of Boyle it should. A real gas is composed of molecules of finite size, and, when these are finally pushed into contact, any further reduction of volume must encounter an enormously increased resistance, and this may set in quite suddenly, as when a fellow is pushed against a wall. However, when the first definite deviations from Boyle's law were found by Regnault in 1847, they turned out to be just the other way around. Instead of a greater resistance at high pressure than the law demanded, less was found. Instead of stiffening enormously, the gases weakened, and the change, instead of being abrupt, was gradual. The effect was most pronounced for carbon dioxide, very slight for air and nitrogen, absent for hydrogen. All this was very puzzling.

The matter was finally cleared up by a remarkable series of experiments begun by Thomas Andrews in 1863 on carbon dioxide. The accidental liquefaction of chlorine gas by Faraday in 1823 had led to the discovery that many gases and vapors

could be liquefied at ordinary temperatures by pressure alone. All efforts, however, on the part of Faraday and of others to liquefy oxygen in this manner failed. And of course no success was had with the other so-called permanent gases. Of the liquefiable gases, carbon dioxide was one of the hardest. It was liquefied by Thirlorier in 1834 at a pressure of sixty atmospheres.
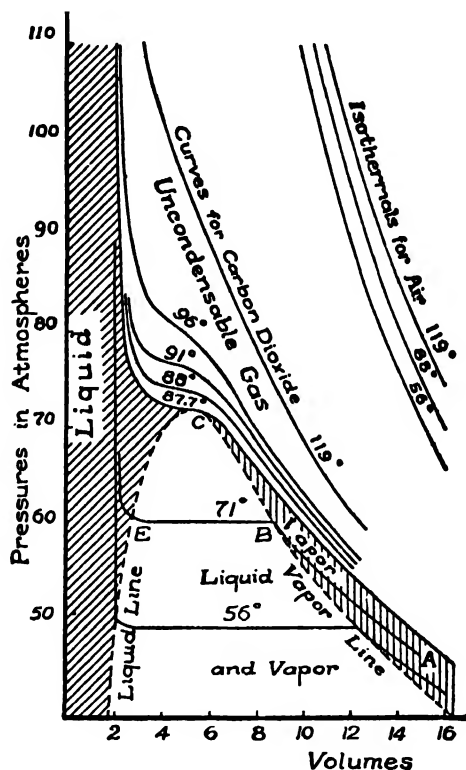

FIG. 31—ANDREWS'S ISOTHERMALS FOR CARBON DIOXIDE

Andrews compressed this gas in a narrow glass tube, at various constant temperatures up to a pressure of four hundred atmospheres, and measured the corresponding pressures and volumes. The temperature ranged from 52 to 119 degrees Fahrenheit. At times the contents of his tube were partly or wholly liquid, at other times wholly gaseous. He plotted the isothermals thus found, several of which are shown in Figure 31.

One may see at a glance that the isothermals of Andrews are

very different in form from those of Boyle, as given in Figure 16, Chapter III—in some cases, indeed, having scarcely any resemblance to them at all. For comparison, three isothermals for air are given, and appear in the upper right-hand corner of the diagram. These obey Boyle's law almost exactly. How close together they are! How widely separated on the other hand are the isothermals for carbon dioxide, for the *same range of temperatures*!

The highest isothermal for carbon dioxide, that for 119 degrees Fahrenheit, resembles, indeed, those for air, but is less steep. This means that, as we proceed up the curve in the direction of increasing pressure, the volume diminishes faster than according to Boyle's law. The gas offers less resistance to compression than it should, as was found by Regnault. The next four isothermals bend first to the left, and then straighten up. This means that there is first a less, then a greater, resistance to compression than required by Boyle. Finally these isothermals rise almost vertically, showing an incompressibility almost as great as that of a liquid, notwithstanding the fact that the substance is still wholly gaseous.

The next lower isothermal at 71 degrees, however, is of an entirely different character. Starting at *A*, far down to the right, and proceeding up the curve, we find that the pressure rises as the volume diminishes, as we should expect of a gas. But at *B* a sudden change takes place. The ascent of the isothermal stops. It turns and runs horizontally to the left, along a constant pressure line. This means that no additional force is now required to reduce the volume by the very large amount represented by *BE*. At *E* conditions are just as suddenly reversed. The line turns sharply upward, and ascends almost vertically. This means that an enormous resistance is now opposed to further reduction of volume. The substance has become almost incompressible. What happened was that at *B* the gas began to liquefy. This proceeded regularly along *BE*, the quantity of gas diminishing, while the quantity of liquid increased. At *E* the liquefaction was completed. Hence a mixture of the two states was present all along *BE*. This is simply our deep cistern barometer experiment of page 70, which the reader will recall showed that, when the temperature is kept constant, the condensation of a vapor takes place at constant pressure. Indeed, the method of Andrews was very

similar, for he compressed his gas by forcing a column of mercury up a narrow glass tube in which the gas was confined. His original apparatus is still preserved in the Victoria and Albert Museum in South Kensington, London.

The process is reversible, as we saw in our barometer experiment. If we start with the liquid in the condition at E, and withdraw the piston or the mercury plug, the liquid vaporizes without change in pressure. After the liquid is entirely vaporized, further enlargement of the volume is accompanied by a decrease in pressure, and we descend the curve BA.

All of the isothermals below 87.7 degrees act in this way. All have straight portions along which liquefaction or vaporization takes place. If we draw a line around these portions, like the dotted one in the figure, we outline a hump-like region, within which the substance is always partly liquid, partly vapor. The left-hand side of this hump we call the liquid line, for to the left of it the substance is wholly liquid. The right-hand side we call the vapor line, for to the right of it the substance is wholly vapor. The hump region, being broad at the bottom and narrow at the top, shows that the difference in volume between the liquid and vapor diminishes as the temperature, and consequently the pressure, rises.

None of the isothermals above 87.7 degrees enter the hump region, and consequently the gas cannot be liquefied at these higher temperatures, no matter how much pressure is applied. This was a discovery of prime importance. The isothermal at 87.7 degrees, which just touches the top of the hump, and thus divides the liquefiable from the nonliquefiable gas, Andrews called the *critical isothermal*. At this point C we have the critical temperature, the critical pressure, and the critical volume of the gas. It is the same point at which the Regnault steam line ends. This line is simply the Andrews hump region seen edgewise, from the reader's right, as will be more fully explained later.

Above the hump, the critical isothermal alone divides the liquid from the gas region. The former has been shaded on the diagram. One should note how closely the isothermals immediately above the critical temperature skirt the liquid coast line, and eventually run almost parallel with it. The gas may here be compressed to a lesser volume, that is, to a greater density, than the liquid has at a lower temperature. Yet it is still gas.

The only way to liquefy the gas at these high pressures is to lower the temperature. That is, we must turn to the left, cross the isothermals, and run toward the liquid coast line.

This explains why all the attempts to liquefy the permanent gases by pressure alone had failed. They were above their critical temperatures. In fact, a few years later, in 1877, came almost simultaneously announcements from Cailletet and Pictet of their success in liquefying oxygen, by a combination of pressure and cold. The critical temperature of this gas was found to be − 180 degrees Fahrenheit.

Since then, all the "permanent" gases have been liquefied, and even solidified. The critical temperature of nitrogen is − 231, that of hydrogen is − 390, and that of helium is − 450 degrees Fahrenheit. Since the absolute zero is at − 460 degrees, helium has only ten degrees in which it can exist as liquid or solid. With these critical temperatures go the critical pressures, which are: for oxygen 50 atmospheres, for nitrogen 33, for hydrogen 30, and for helium only 2.3. It should be noted that these pressures are not high, and any greater pressures do not help liquefaction in the least. Hence, it is not high pressure, but extreme cold that is required to liquefy the "permanent" gases. Indeed, with modern technic, it is now possible to liquefy all of these gases without compressing them at all, by simply cooling them to their boiling points, which are also their condensing points, at atmospheric pressure. These are for the gases mentioned in order: − 297, − 320, − 423, − 451.5 degrees Fahrenheit.

For these permanent gases we must imagine the hump of the Andrews diagram shrunk to a very narrow region in the lower left-hand corner. For helium it becomes a tiny spot indeed. On the other hand, for a substance like steam, whose critical temperature is 689 degrees Fahrenheit, and whose critical pressure is 195 atmospheres, the hump region rises and spreads out far beyond the limits of this diagram. It has a huge area. For substances that are ordinarily solid, like iron, the critical temperatures and pressures of their vapors are still higher. There is hence a tremendous variation in the height and area of this hump region for different substances.

Before the time of Andrews, the distinction between a gas and a vapor was rather nebulous. At first it was thought they were radically different things. A vapor was something that was

given off by a liquid, or into which a liquid could be converted by heating. Such was steam. Conversely, a vapor could always be condensed into a liquid by cooling or compressing, which was impossible for a gas. But when it was found that many gases could be liquefied by pressure alone, it was thought that there was no distinction. Gases and vapors were the same. The idea did not work, however, in the case of oxygen. Andrews was able to give a clear distinction. A vapor, he said, is simply a gas that is below its critical temperature, and is therefore liquefiable by pressure alone. It is a gas in the region, lightly shaded with vertical lines in Figure 31, which lies between the critical isothermal and the right-hand side of the hump.

The weakening which Regnault observed in the permanent gases at high pressures, was just the beginning of the bend to the left in Andrews's curves. Had Regnault carried his pressures higher, up to eight hundred atmospheres, as Amagat did in 1880, he would have found that the gases stiffened again at the higher pressures. Hence the weakening was only temporary. An isothermal, as it passes near the critical point, bends toward it as though attracted by it, but straightens up after passing. As we recede from the critical point, the bend in the isothermals gradually smooths out, as though the attraction of this point diminished with the distance, and at last became impotent. Regnault found a considerable weakening in carbon dioxide, because he was not far above the critical point of that gas. He found less for air because he was farther from its critical point. He found none for hydrogen because he was so far above its critical point, that the bend had quite disappeared. It can be found, however, at a lower temperature,

What is the condition of a substance at the critical point? Just below, in the hump region, it is a mixture of liquid and vapor. Just above, it is wholly gas. What would happen if we passed directly through that point? It can be done in the following way:

Suppose we have a substance in the condition represented by the point A of Figure 32, a mixture of liquid and vapor at ordinary temperature and pressure. We enclose it in a strong vessel hermetically sealed, and raise its temperature. By this process we ascend the constant volume line AC, and if the heating is continued long enough we pass through the critical point

C. At any point within the hump, the proportions by weight of liquid to vapor are given by the distances of the point from the right and left sides of the hump respectively. We see that as we ascend *AC* these proportions do not change materially. Just below *C*, they are about the same as at the start—as much liquid as ever on hand. At the moment of passing through *C*, all of this liquid must be converted into gas—and uncondensable gas at that. What happens? A fearful explosion?
FIG. 32—HOW TO PUT A SUBSTANCE THROUGH ITS CRITICAL POINT

By no means! What is an explosion? A great and sudden rise in pressure, as in the cylinder of a gas engine, or a huge expansion in volume, as when a boiler bursts. But there is here no sudden rise in pressure. As read off on the left-hand vertical scale, the pressure rises steadily as we ascend *AC*, the rate being perfectly controlled by the rate at which we supply heat. Just above *C*, the pressure is only slightly greater than just below *C*, and has increased no more than over a stretch of similar length elsewhere along *AC*. If the vessel can withstand the pressure in this neighborhood, there is no more danger of explosion than if we had simply compressed air up to this pressure. In fact, nothing violent happens, and the change is more gradual and prolonged than one would suspect. What does happen, however, is very interesting, and cannot easily be foreseen. Let us therefore try the experiment.

For this purpose we shall not use carbon dioxide, as Andrews did, but ether, which has the advantage of being already liquid at atmospheric pressure.   Its critical temperature is 387 degrees Fahrenheit, its critical pressure thirty-six atmospheres.   The ether is sealed in a small glass tube, as at *A*, Figure 33, in such a way that about two-thirds of the volume is liquid, the rest vapor.   The tube is then immersed in a bath of olive oil, which is heated.   Since the boiling point of the oil is 570 degrees, it is well above the critical temperature of the ether at which we wish to arrive.

At the start of the experiment, the surface of the liquid ether is clearly seen, and is decidedly concave.   This is due to *adhesion* of the molecules to the walls of the tube and to *cohesion* among themselves, as will be more fully explained in Chapter XIII.

A   B   C   D
FIG. 33 —THE CRITICAL TUBE

As the heating proceeds and the molecules become more agitated, they stick less readily either to the tube or to one another. Both adhesion and cohesion diminish.   The curvature of the surface becomes less, until, as at *B*, the surface becomes entirely flat and barely visible.   The molecules have ceased to adhere to the tube, and barely cohere to one another.   As we pass through the critical point, the surface becomes hazy.   It thickens into a sort of turbulent cloud belt, as at *C*.   This expands and fades rapidly until the whole tube seems to be filled with a faint haze.   A moment later it is clear, as at *D*. It is now completely filled with gas.

If we now lift the tube from the hot bath and allow it to cool, the reverse changes occur.   A faint haze first appears throughout the tube, and seems to rain in both directions toward the middle, quickly condensing into a cloud belt, which in turn contracts until the thin flat surface is again formed at precisely the same spot at which it had previously disappeared.   To see the rain ascending to re-form the cloud, and the whole series of events reversed, is like seeing a movie run backwards.   As cooling further proceeds, the surface becomes more and more distinct and curved, until the original condition at *A* is restored.

During the ordinary process of boiling at constant pressure, the liquid vaporizes bit by bit, the surface of the liquid descending slowly until it reaches the bottom of the vessel. During the constant volume process that takes place in the critical tube, the surface of the liquid does not descend, but rather ascends slightly; for the density of the liquid diminishes, while that of the vapor increases, until at the critical point both have the same density, and this condition remains unchanged with further heating. Nevertheless, the approach to the gaseous state is as gradual and prolonged and even more so than in the case of ordinary boiling. It takes place throughout the mass of the liquid, and begins with the first heating. The molecules of the liquid elbow themselves farther and farther apart, while those of the vapor become more and more compacted, until at last there is no distinction between them, and the line of demarcation disappears. No latent heat is required to pass from liquid to gas in this way.

It is also possible to carry a substance directly across the coast line of the critical isothermal at a point above the hump region. This, in fact, was done by Andrews in the course of his experiments on carbon dioxide. The gas was first heated above its critical temperature; then, keeping the temperature constant, it was compressed until it was as dense as the liquid is at a lower temperature. This condition is represented by such a point as B, Figure 32. The gas was then cooled at constant volume, and thus descended the line BD into the liquid region. There is nothing spectacular about this experiment. Nothing apparently happens as the critical isothermal is crossed. There is no conspicuous change in appearance to indicate the moment of this crossing. The tube remains clear and homogeneous throughout the whole experiment. Yet at B it is filled with gas; at D it is filled with liquid. There are, however, slight changes. The liquid refracts the light, and so magnifies objects held behind it. But a conclusive proof was given by Andrews, by relieving the pressure at D while keeping the temperature constant. In this way he descended the isothermal DE. As the hump region was entered, the liquid began to boil in the usual way. Bubbles rose from its interior, the surface soon appeared at the top of the tube and slowly descended until it reached the bottom, and the space above, now much enlarged by the withdrawal of the piston, was entirely filled with vapor.

It is rather difficult to state just what the difference is between the gas at *B* and the liquid at *D*, for both have the *same density*. This means that the *average* distance between the molecules is the same for both. But at *B* the variations in distance are greater. Some of the molecules will have jostled their neighbors, for the moment, out of the way, and so have gained room for free flights. Offsetting this, there will be at other places temporary overcrowdings. But the scene is constantly shifting, so that every molecule, at one time or another, gets a chance for a free flight, which is the birthright of every gaseous molecule. In the body of the liquid, the variations are less. No molecule ever gets away from the grasp of its neighbors. It may wiggle a little within that grasp, but can never indulge in a free flight. The ultimate difference, then, between a gas and a liquid is the presence or absence of molecular free flights.

These experiments impressed Andrews with what he called the "continuity of state." However greatly liquids and gases may differ in appearances and properties under ordinary circumstances, they are, he said, ". . . only distant stages of a long series of continuous physical changes." They "may be made to pass into one another by a series of gradations so gentle that the passage shall nowhere present any interruption or breach of continuity." "But," he said, "a problem of far greater difficulty yet remains to be solved, the possible continuity of the liquid and solid states of matter."

This problem has been partially solved. With the help of a triple-point diagram, we can extend the Andrews isothermals to include the solid state. For this purpose we shall choose a substance like paraffin which contracts on solidifying. Figure 34 is the diagram for such a substance. It is the same as Figure 25 in Chapter VI, except that the "ice line" here leans to the right, in the direction of increasing temperature, because increase in pressure now raises the melting point. Figure 25 was for a substance like ice that expands on solidifying, so that increase of pressure lowered the melting point, and the ice line there leaned to the left.

On these *pt* diagrams, an isothermal is a straight vertical line. If the ice line leans to the right as in Figure 34, isothermals like *ABDE* above the triple point, will traverse all three states. Thus *AB* is in the vapor, *BD* in the liquid, *DE* in the solid region. As we compress the vapor along *AB*, liquefaction

occurs at *B* with a large reduction in volume. By further com-
pressing the liquid along *BD*, solidification occurs at *D* with a
small reduction in volume. By further compression of the
solid, we simply ascend *DE*. But these volume changes of
course do not show on this diagram. They do show, however,
in Figure 35, which is a *pv* or Andrews diagram for the same
substance, and the isothermal *ABDE* there appears with the
same letters. The point *B* of Figure 34 here becomes the *line*
BB'. The point *D* of 34 here becomes the *line DD'*. *BB'*
FIG. 34—TRIPLE POINT DIAGRAM FOR A SUBSTANCE THAT CONTRACTS ON SOLIDIFYING

is our familiar liquefaction line across the hump region. But
we now see that the isothermal, after ascending the liquid
region some distance, meets another transformation area at *D*,
the solid-liquid region. Here the substance contracts as it
solidifies without change in pressure. When solidification is
complete, the isothermal again ascends almost vertically in the
solid region.

All the isothermals between the triple and the critical points
act like *ABDE*, as may be seen from the several that have been
drawn in Figure 35. An isothermal above the critical point
misses the liquid region entirely; but it will still hit the ice line
at some stupendous pressure, provided this line continues inde-
finitely to lean away from the reader. We have then this
curious result, that, although it is impossible to liquefy a gas
that is above its critical temperature, it may be perfectly
possible to solidify it!

As we go down temperature from the critical to the triple point, the liquid portions of the isothermals become shorter and shorter, until at the latter point they reduce to nothing.   But the triple point, which is T in Figure 34, becomes the triple *line* TT'' in Figure 35, and a very long one at that, for it includes not only the contraction from vapor to liquid TT', but also the additional contraction from liquid to solid $T'T''$.   The liquid-solid transition area springs from this segment $T'T''$, and runs
like a narrow ledge up the diagram.   Every liquid isothermal that meets this ledge drops down it to the solid region below— or, rather, to the left.   Below the triple line, the widened hump region represents a mixture of vapor and solid, and the direct transition from one to the other.

For a substance like ice that expands on freezing T'' would lie to the right of T', and the area below the triple line would be

narrowed instead of widened. The solid-liquid ledge would still spring from $T'T'''$ as before, but since it would lean toward instead of away from the reader, the isothermals that traverse the liquid region would not meet it. Only those below the triple line, which run up the ice region, would meet it, and would then drop off into the liquid region, which now has the lesser volume. But because the projecting ice would hide a good part of the liquid region, this case cannot be satisfactorily represented on a diagram such as Figure 35.

The complete Andrews diagram is thus seen to consist of three regions representing vapor, liquid, and solid, and three transition areas, where the changes from one to the other take place. The Regnault diagram consists of the same three regions, and three transition *lines*, where the same transformations take place. Evidently the two diagrams are only different presentations of the same thing. In fact, the one being a *pv*, the other a *pt* plot, they are related in the same way as the Boyle and Gay-Lussac diagrams of Chapter III, and may be combined into a single three-dimensional model in the same way.

To do this, we must imagine a temperature axis starting from the lower left-hand corner of Figure 35, and receding from the reader, and each isothermal set back a distance proportional to its absolute temperature. We then see that the Regnault diagram is simply this model looked at from the reader's right. The Andrews transition areas are then seen edgewise and become the transition lines of Regnault. The isothermals where they cross these areas are seen end on and become points; the isothermals themselves become lines straight up and down. The Andrews diagram is a front view of this model.

But let us relieve our imaginations from further strain by actually constructing the model. We shall not, however, use carbon dioxide, nor the imaginary substance of Figure 35, but that substance which is most abundant and useful in this world and about which we possess the most extensive and accurate information, namely—water. This will enable us to plot the isothermals to scale. Then having set them up in the manner described, we give the model one-eighth of a turn to the left, so that the projecting ice region will not hide so much, and the result appears as in Figure 36.

This model shows in a single view all the known forms of

water, ice, and steam, including Bridgman's five forms of ice. On account of the enormous ranges of pressures and volumes involved, it has again been necessary to use scales that greatly compress the higher values. The cube roots of the temperatures, the fourth roots of the pressures, and the tenth roots of the
FIG. 36—MODEL FOR WATER, ICE, AND STEAM

volumes have been plotted. These scales do not destroy the essential relations, but rather make it possible to bring them all into a single view. Compression of the volumes is particularly needed. The volume of ice at 32 degrees Fahrenheit is 0.0175 cubic feet; that of steam at the same temperature is 3294 cubic feet, or nearly two hundred thousand times greater. If the

former volume were represented by only one-tenth of an inch, the latter would require on the same uniform scale nearly one-third of a mile. That would be the length of the triple line. It would be a little difficult to fold that up into a book. On the scale chosen instead, the two volumes are represented by lengths that are in the ratio of about one to four. Even at that, the steam line runs off the model a little below 32 degrees, so that the enormous expansion that occurs when ice passes directly into vapor at low temperatures cannot be shown. On the other hand, the changes in volume between the different kinds of ice are so small that it has been necessary to magnify them ten times.

The model has been cut off at −60 degrees, for the scales stretch out the low regions as much as they compress the high ones, and the absolute zero lies far forward to the left. The ice-steam area continues down to the absolute zero forming an exceedingly thin wedge. So far as known, nothing of interest occurs in this region anyway. The model has also been cut off at 0.0001 cubic foot. To continue it to zero volume would only inconveniently thicken the left back wall. The pressure or vertical axis alone has been brought down to zero.

In the upper left-hand corner of the model are Bridgman's four new forms of ice. These are all less in volume than water, and hence become sunk in areas, separated from the water region by the ledge that runs upward and to the right. Ice I, or ordinary ice, is represented by the pillar at the bottom. It is really a sheet that extends forward and leftward to the absolute zero. This ice being greater in volume than water, the ledge that separates it from the latter projects outward from the water surface. The ordinary ice line is hidden behind the pillar, and has been shown dotted. The ordinary triple point T_0 lies at the bottom of the pillar, T_1 at the top. T_2 and T_3 lie farther up on the ledge. The pressures corresponding to these triple points are marked on the diagram. They are the same points that appear in Figures 26 and 27.

It is interesting to follow the −60 degrees isothermal, which forms the left front boundary of the model. This isothermal, after traversing the ice-steam surface, ascends the pillar of ice I, then crosses in succession ices II, V, and VI, thus crossing four kinds of ice. At each junction there is a contraction in volume.

This model, which portrays the behavior of a real gas, should

be compared with the one on page 36, which sets the standard of perfect behavior. This one is very different in appearance and much more complicated. Yet the complications fade out gradually as the temperature rises, and above 1200 degrees Fahrenheit the isothermals are quite smooth, and approach in form those of Boyle.

XII

BOILING BY BUMPING

THE model described in the previous chapter shows the actual behavior of a real substance in its various states. It is, however, purely empirical, that is, it is simply a résumé, an exhibition of what we know about the substance. An immense amount of experimental data was required for its construction, data that scientists have been gathering ever since the days of Regnault in 1847. We possess enough such information for a fairly complete model only for the substance water.

The model of Chapter III for a perfect gas is a purely theoretical construction. The whole thing is developed from the single equation $pv = RT$, and if all gases were perfect, we would only have to determine by experiment the value of the single constant R for each gas, and then the complete behavior of every gas under all conditions and circumstances could be calculated. That would save an immense amount of experimental work and uncertainty. Despite the great mass of data that has accumulated, it often happens, when some new problem or new industrial development comes up, that the data required is lacking, or has not been determined with sufficient accuracy, or, if it has, is so buried amid mountains of other data that it cannot be found, and new measurements have to be made. Hence the physicist would like to develop a theoretical model that approximates somewhat more closely to the actual behavior shown in Figure 36, and that does not ignore the changes of state, as the perfect gas model of Figure 18 does. Of course he cannot expect, with these added complications, to get out of it with so simple an equation as that for a perfect gas, nor to be able to make everything depend upon a single measurement for each gas. But if he could obtain a good approximation to any considerable part of the model of Chapter XI, that would take account at least of liquefaction, and would require only a few

measured constants, he would feel that a great forward step had been made.

One trouble with the model of Chapter XI is its many discontinuities, that is, sharp corners. Every isothermal that passes through the hump region consists of at least three parts, one in the vapor, one in the liquid, and one in the transition region. Each part follows a separate law, hence requires a separate equation. But if these sharp corners could be gotten rid of, so that each part passed more or less gradually into the next, then the whole of such an isothermal could be represented by a single equation. The first step, then, toward our goal is to get rid, if possible, of these sharp corners, to make each isothermal a process of *continuous* change from end to end.

We believe, in fact, that this would more nearly represent what actually occurs, for we believe that nature does nothing suddenly. We have seen that amorphous substances do not have the sharp melting points that crystalline ones have, but rather places of more rapid change. It may be that the melting points of crystalline substances are not as sharp as they appear to the unaided eye, that if we could look at them with a magnifier, as it were, we would find them rounded, to be also places of more rapid but not of instantaneous change. Let us examine, then, a little more closely just what happens when a substance changes state.

Ordinarily when water is cooled, the fall in temperature stops when the freezing point is reached. Ice crystals then begin to form and the temperature remains constant so long as the freezing continues. But if pure water in a perfectly clean vessel is cooled very quietly, it is possible to reduce the temperature much below the freezing point without solidification occurring. This is called *undercooling*. Despretz succeeded in this way in cooling water to −4 degrees Fahrenheit without freezing it. The undercooled water continued to expand and to increase in viscosity as the temperature fell, just as it did in approaching the freezing point. If during the process, however, there is the slightest jar, or a bit of ice is dropped into the liquid, a considerable amount of water freezes at once, and the temperature immediately rises to the ordinary freezing point. This rise is due to the latent heat released by the sudden solidification, which warms the liquid.

An undercooled liquid is thus in a state of unstable

equilibrium, which grows more acute as the temperature falls. With most liquids, a point is at last reached where spontaneous crystallization occurs, whether there is a disturbance or not. The crystals start at innumerable points distributed throughout the liquid and grow rapidly out from these as centers until the whole mass is solid. This process has been followed with the microscope. The number of points and the rate of growth are characteristic of the substance. If solid impurities are present, the crystals form around these as nuclei, and the process begins much sooner.

It appears, then, that the freezing of a liquid at its freezing point, though the *usual*, is not the *normal* process. It is due solely to impurities and disturbances. The normal course for the pure and undisturbed liquid is to cool further to the temperature of spontaneous crystallization, and then solidify rapidly *en masse*. And the latent heat of fusion is not released until this crystallization occurs, no matter how much the liquid has been undercooled. This normal behavior is unusual only because impurities and disturbances are usual.

It is further apparent that, because of the impulse and time required for the growth of a crystal, all freezing, even that of the usual sort, must be accompanied by some undercooling, although it may be very small and occur at innumerable points. A crystal simply will not form unless there is a nucleus, or a definitely indicated point for starting, and an impulse provided by the tension of an undercooling. In fact, when measuring melting points, or when fixing the zero point of a thermometer by a mixture of melting ice and water, it is important to stir the mixtures constantly, in order to avoid appreciable undercooling at any point.

Chemists are familiar with a similar phenomenon when a substance crystallizes out of solution. A pure saturated solution may be quietly cooled, and thereby become supersaturated. But if a crystal of the substance is dropped into the liquid, a considerable amount crystallizes out at once, and the temperature rises to that at which the solution is again saturated.

While it is difficult to undercool water and substances like it to any great extent, there are others for which it is difficult and even impossible to avoid undercooling. With all substances the tendency to crystallize increases as the temperature is lowered under the ordinary freezing point. But with these

other substances the tendency reaches a maximum value at
some point, and thereafter diminishes as the temperature is
further reduced.   If this perilous stretch can be safely run
through, by rapid and quiet cooling, the temperature can then
be lowered indefinitely without further danger of crystallization
occurring.   Nevertheless, the substance does not remain liquid.
It solidifies with its molecules, so to speak, in place, precisely
as they were in the liquid state.   This process is analogous to
the liquefaction of a gas with its molecules in place, as was
described on page 104.   And as in the latter case there was no
conspicuous change in appearance as the gas became liquid, so
in this there is no conspicuous change as the liquid becomes
solid.   There is no sudden change in volume, no release of a
latent heat.   The properties of the substance change contin-
uously, though more rapidly than at other temperatures.   The
substance simply becomes more and more viscous until it
becomes hard.   The solid is isotropic and clear like the liquid,
only it refracts the light more strongly.   It is hard, brittle, and
when broken the fracture is smooth and without grain or facets.
The substance is a glass.

    That glass is simply an undercooled liquid, that has belatedly
solidified, is shown also by the fact that it sometimes does
crystallize and solidify prematurely, much to the chagrin of the
glass maker.   This crystallization can, indeed, be induced by
the addition of certain substances called mineralizing agents.
They convert the glass into an opaque crystalline mineral.

    In the same way that a liquid can be quietly cooled below its
usual freezing point, it can also be heated above its usual boiling
point.   Thus if pure water, from which the dissolved air has
been driven off by previous boiling, is quietly heated in a clean
flask, especially if the heat is applied from all sides by immersing
the flask in an oil bath, the temperature can be raised much
above the boiling point without boiling occurring.   Dufour,
by heating small drops of water immersed in a mixture of oils
of the same density, was able to raise the temperature to 317
degrees Fahrenheit without their boiling.   If, however, the
superheated liquid is disturbed, or a foreign object dropped into
it, a large bubble of steam forms all at once and the temperature
drops to the boiling point.   Bubbles of steam will then continue
to rise from the foreign object introduced, and if this has any
sharp edges or corners, the bubbles form more readily at these

places, and are then smaller and more numerous.   If no foreign object is introduced, the temperature will continue to rise until suddenly an enormous bubble is formed and ejected with explosive violence.   Then the liquid quiets down, the temperature again rises until another big bubble is formed and violently ejected—and so on.   This process is called *boiling by bumping*. It got its name from the fact that it sometimes occurs in steam boilers, when, from the clogging of the tubes or other causes, proper circulation of the water is prevented.   The intermittent boiling produces sudden rises of pressure, and a bumping noise. It is not good for the engine and may be dangerous.   It signifies that the boiler should be cleaned at once.

This boiling by bumping, like the undercooling, though not the usual process, is nevertheless the normal one.   The ordinary quiet boiling is due to disturbances and foreign bodies. Fortunately our pots and kettles are sufficiently rough to provide innumerable points where bubbles may easily form, and so the boiling is quiet.   But the phenomenon is not so rare in the case of viscous liquids, which do not circulate freely.   Watch a pot of thick porridge on the stove.   Note how the middle slowly rises in a hump, breaks, and emits a big puff of steam from a crater-like opening, then subsides only to repeat the process over and over.   The housewife knows that it is high time to apply artificial circulation in the form of vigorous stirring, else the porridge will burn.   By so doing she keeps the bubbles small.   They are then more frequent, and the rise in temperature between bumps is reduced.

In the end, all boiling is by bumping.   Every individual bubble, however small, involves an overheating of the fluid in its neighborhood, a rapid conversion of a finite quantity of it into steam, and a consequent drop in temperature to the normal boiling point.   Every bubble requires something on which to form.   None forms in the middle of the liquid, unless there are solid particles floating about.   Otherwise they all form on the bottom or sides of the vessel, especially where there are rough places or projecting points.   If there is a sufficiency of these, the boiling is quiet and steady.

Because some slight bumping and overheating are always present even during the quietest boiling, when measuring the boiling points of liquids or determining the steam point of a thermometer, we place the thermometer, not in the liquid, but

in the vapor just above it. This has the same temperature, but is not subject to the fluctuations caused by bumping. In the case of solutions, however, we cannot do this, because the thermometer then registers the boiling point of the solvent, not of the solution, as already explained. The instrument must be placed in the liquid. To insure, then, as even and quiet boiling as possible, a quantity of broken glass or crockery or sand is placed in the solution.

Similar phenomena occur during condensation. The pure vapor can be compressed beyond the saturation pressure, or the temperature reduced below the dew point, without condensation occurring. But if smoke, dust particles, liquid particles, or ions (electrified atoms), are introduced, a cloud immediately forms. The vapor condenses on the foreign particles as nuclei, and they seem to be necessary to the formation of a cloud.

These facts have led some people to believe that by discharging smoke, dust, or electricity into the air, rain could be produced. But this can only succeed if the atmosphere is already supersaturated, in which case it will presently rain anyway, and the rain maker is unnecessary. The method can sometimes be used, however, to precipitate a fog.

Another favorite method has been to shoot bombs up into the clouds, with the idea that the explosions would somehow coagulate the droplets, instead of scattering them as might more reasonably be expected. The idea seems to be based on reports of rains that have followed battles, or on the observation that rain frequently falls just after a heavy clap of thunder. With regard to the latter, it must be remarked that, since the sound reaches us very quickly, while the rain takes some time to fall, it is more likely that the rain started first and provided the semi-conducting path that enabled the big flash to occur. The cart has been put before the horse. With regard to more occult methods of producing rain, nothing need be said.

In 1871 James Thomson, the brother of Lord Kelvin, suggested that these phenomena of supersaturation, etc., would be more closely represented by isothermals of the form shown in Figure 37, than by those of Andrews. Starting with the vapor at A, and compressing isothermally along AB, condensation does not begin at B, but the pressure continues to rise until D is reached. Then a considerable amount of vapor condenses all at once, while the pressure falls and then rises again finally

to the value corresponding to the boiling point. Or starting
with the liquid at *H*, and heating along the constant pressure
line *HKL*, boiling does not begin at *K*, but the temperature con-
tinues to rise, for the line crosses the higher isothermals until
we come to the center of the depression at *L*. Then we recross
the same isothermals in the reverse order. The temperature is
now falling, and vaporization occurs.
FIG. 37—JAMES THOMSON'S ISOTHERMALS

These isothermals of Thomson are continuous curves.
Hence they are such as can be represented throughout their
entire lengths by a single mathematical equation. If an
equation could be found to fit them and also conform to the
requirements of gases, the aim of the theoretical physicist men-
tioned at the beginning of this chapter would be partially
realized. Such an equation, in fact, was found by the Dutch
physicist, Van der Waals, in 1879. He reflected that the
theory of perfect gases is based on the assumptions that the
molecules have no size, and that there are no attractions be-
tween them, both of which assumptions are false. The mole-
cules certainly have size, and determine a minimum volume for
the gas. Since the molecules cohere strongly when in the
liquid and solid states, there must also be attractions between
them; and while these forces may be very feeble when the mole-
cules are far apart, they doubtless become of importance when
the gas is concentrated and approaches its liquefaction point.
Their effect would be to diminish the pressure which the gas

exerts by virtue of the impacts of its molecules on the walls of the containing vessel, for a molecule cannot strike so hard if held back by its neighbors. Van der Waals therefore introduced into the perfect gas equation $pv = RT$, two new terms to correct for its two false assumptions. These involved two new constants, so that his equation contains three constants, to be determined by experiment for each gas, instead of the one constant R of the old equation.[1]

Van der Waals's equation gives below the critical point isothermals greatly resembling those of William Thomson, and above this point isothermals closely resembling those of Andrews. If the temperature is further raised, the isothermals gradually approach the form of those of Boyle. Thus the behavior of a gas, both far above and considerably below its critical point, is very faithfully represented. But quantitatively the agreement with experiment is not as good as could be desired. Other and more complicated equations have been proposed, and some of them are more exact than that of Van der Waals; but they involve additional constants and arbitrary assumptions that have no direct physical meanings. They are empirical formulations that have simply been fitted to the facts, and so represent no theoretical advance.

A complete equation of this sort should of course include the solid state. But here the complications, with the many crystalline and amorphous forms, are much too great. Besides, we have not yet enough knowledge. A great deal of research is now being done on the solid state, aided by X-ray analysis and other powerful new weapons. But so far the results have only been to uncover endless new details and complications, which give rise to innumerable new theoretical problems. And it

---

[1] Van der Waals's equation is $(p + a/v^2)(v - b) = RT$; a and b are the two new constants to be determined by experiment; b is simply the minimum volume of the substance, the space occupied by it when the pressure is infinite. Then $(v - b)$ is the additional space occupied by the molecular motions. This subtracting out of b is equivalent to moving the pressure axis of the diagram a distance b to the left. The strip of space thus set off is never invaded by the isothermals produced by the equation. The term a/v^2 is the additional restraint put upon the motions of the molecules by their mutual attractions. It is equivalent to a pressure which is added to the external pressure. Since each molecule attracts every other, Van der Waals assumed that this additional restraint would be proportional to the square of the density, that is, inversely proportional to the square of the volume of the gas. When the volume becomes very large, the value of this term becomes very small, so that the isothermals of Van der Waals then approximate to those of Boyle.

appears that there is still an immense amount of fine detail
that lies beyond even the reach of the X-rays, to which we have
only just begun to penetrate.   We cannot, of course, begin to
form a comprehensive theory until a good part of the facts con-
cerned are at hand.

I sometimes wish that those philosophers who preach so
powerfully about unity, and about its desirability, as though
we had only to wish for it in order to have it, would try their
hands at unifying the solid, liquid, and gaseous states of matter.
Unity is easy to achieve when one's eyesight is poor, and all
things look alike anyway.   But when one's vision is sharpened
by high-powered microscopes, and by instruments and methods
that probe many times more deeply, he discovers such endless
differences and variations, that to bring unity into only a
minute fraction of them is the work of a lifetime.   The scientist
who, more than any one else in the world, is laboring to bring
unity out of chaos, talks very little about it.   He hasn't the
time.

XIII

MOISTURE

WHAT do we mean when we say that water is wet? We mean in general that it will adhere to the fingers or to other solid bodies that are dipped in it, forming a thin film over their surfaces. Other liquids are wet in the same way. On the other hand we say that mercury is dry, because it does not stick to the fingers, to glass, to cloth, or to many other objects. We usually think also that a liquid that is wet is always wet, and one that is dry is always dry. But this is not so. Water will not stick to a greased surface, but gathers itself into little globules, as though it were repelled by the grease, and were trying to get as far away from it as possible. Water runs off a duck's back. On the other hand, mercury sticks very strongly to clean metallic surfaces, and forms a film over them just as water does when it wets an object. Nevertheless, we do not call this wetting, but amalgamation—perhaps because we cannot wipe the mercury off with a rag, as we can water. But this is only because mercury does not wet the rag as water does. Obviously two substances are always concerned in the matter of wetting, the one that wets and the one that is wetted; and no liquid is universally wet, nor is any universally dry.

Wetting is due to the attraction or adhesion between the molecules of one body and those of another. This attraction is always present; nevertheless wetting does not always occur. In order for it to occur, two things are necessary. First, the two bodies must be brought into very close contact over considerable areas, because the molecular attractions are effective only at very short distances. The molecules of different solids, for example, attract one another. But the surfaces of solids, even when they appear quite smooth, are, molecularly speaking, rough. Two such bodies come into intimate contact only at isolated points. The *adhesion* produced by these few points

is too feeble to be effective. But when two pieces of glass are ground optically flat, and the surfaces are perfectly clean, then when they are pressed and wrung together, they adhere with a very appreciable force. A liquid, on the other hand, flows into every irregularity of a solid, and so comes into intimate contact over large areas. Hence it can adhere strongly. If the wetted surfaces of two pieces of glass are brought together, even if their surfaces are far from being optically flat, they will adhere strongly. They will slide easily on one another, but to pull them directly apart requires considerable force.

The second condition that must be fulfilled if a liquid is to wet a solid is that the attraction between its molecules and those of the solid must exceed the attractions between its own molecules. In short, the *adhesion* must exceed the *cohesion*. For the molecules to stick to a foreign object, they must be drawn away from their fellow molecules—the foreign attachments must exceed the home ties. If the reverse is true, the liquid draws away from the foreign object, not because there is a repulsion— for there is not—but because the home ties are stronger, as illustrated by the way water on a greased surface draws itself up into globules.

A further illustration is afforded by the behavior of liquids in tubes of small bore, especially in *capillary* or hairlike tubes. If such a tube is dipped in a liquid which wets it, the liquid is drawn a short distance up the tube, not only against gravity, but against the restraining attraction of the rest of the liquid, and the surface is concave, as shown at *A* in Figure 38. If, on the other hand, the tube is dipped into a liquid which does not wet it, like glass in mercury, the liquid is depressed in the tube, and the surface is convex, as at *B* in the figure. There is still attraction between the mercury and the glass, but the attraction of the rest of the mercury in the vessel is the stronger, and is able to pull some of the mercury down out of the tube. A rag is an excellent wiper for liquids that wet it because its many interstices form so many capillary tubes into which the liquid is drawn. But it will not wipe mercury because the latter is not drawn into these tubes.

We also distinguish degrees of wetness. We say that a body is saturated, is sopping or wringing wet, when it is as wet as it can be. When less wet we call it moist or damp. But in every case we mean the presence of more or less liquid. Hence wet-

ness is something that pertains to liquids. In the following we shall further confine ourselves to the wetness that is produced by water.

Nevertheless there is a general notion that ice and steam are also wet—in short, that water in all its forms is wet. The idea arises perhaps from the fact that all three forms wet the fingers. But ice does so because of a film of water that is produced by its melting, and this is caused either by the higher surrounding temperature or by the warmth of the fingers themselves. Ice below the freezing point is perfectly dry. On the other hand, steam condenses to water on the fingers because the latter are cooler. The steam before it condenses is perfectly dry, for if we put a dry object in it, which is at the same or a higher temperature, the object will remain dry. In both cases the wetting was done by water. Of the three forms, then, water alone is wet, and does all the wetting.

Steam in fact is a gas, as dry and invisible as air. The white clouds that we see issuing from a steam pipe are not steam, but are composed of fine particles of water into which the cooled steam has condensed.

FIG. 38—CAPILLARY ELEVATION AND DEPRESSION

If we boil water in a glass flask, as in Figure 39, the interior is perfectly clear, and nothing is seen of the steam until this cloud is formed. If the steam issues rapidly from a fine nozzle, a transparent space may often be seen between the nozzle and the cloud, where the steam has not yet condensed. Afterwards the cloud disappears, which means that the water reëvaporates, and becomes again invisible steam, but at a lower temperature and pressure. All fogs, clouds, and mists are composed of fine particles of water or of ice. All vapors are dry, being merely gases below their critical temperatures. There are no "clouds of steam."

Yet the engineer often speaks of *wet steam*. Now how can steam ever be wet, if all vapors are dry, and all wetting is done by water sticking to the object wetted? Do we mean that molecules of water attach themselves to a molecule of steam and wet it? That would be absurd, because there is no difference between a molecule of water and one of steam. When the

molecules are flying about freely and separately, they are steam. When a number are clumped together, they become a drop of water, and there is no distinction between the molecule that is wetted and those that are doing the wetting. Nevertheless, something of the sort we do mean. Steam is wet when a certain amount of water in the form of a fine mist is intimately mixed with it. The degree of wetness is measured by the percentage of the mixture by weight that is water.

This "mixture" must be distinguished from that represented by a point on the Regnault steam line, or within the hump region of the Andrews diagram. In this latter mixture, all of the water is at the bottom of the vessel, all of the steam is at the top. The two are *separated* by the liquid surface. Steam in this condition, in contact with its liquid, but not mixed with it, is dry and saturated— saturated, not because it contains any water, but because it is just ready to condense.

We speak also at times of a gas being moist or humid, of the air being damp. Do we mean that a certain amount of water is intimately mixed with it, as in the case of wet steam? Do we mean that when such air comes in contact with an object, it will moisten it? By no means! Such air will dry the object. For instance, the washerwoman tells us that the air is very damp to-day, because it takes a long time for the clothes hung out on the line to dry. Nevertheless they *do* dry. Damp air, then, has no wetting power, but only a *diminished drying power*. And this is due, not to the presence of water, but of water vapor, which impedes evaporation. The air is dry, the vapor is dry, hence the whole mixture is dry, and has drying power.

Nor is the so-called dampness measured even by the proportion of the mixture that is water *vapor*. A given mixture, when simply heated, becomes drier, in the sense that its drying power is increased, although the proportion of the ingredients is not changed thereby. Thus the laundry man, when it is too damp

FIG. 39—STEAM IS INVISIBLE

outside, hangs his clothes up in the hot room, where he uses the *same* air to dry them, but heats it first. Now this heating can in no wise destroy any of the water vapor present, nor convert it into anything else. Furthermore, both the air and the vapor were already perfectly dry, hence cannot be made any drier by heating. Yet the drying power of the mixture is undoubtedly increased. What is the explanation?

In the first place, the air has nothing to do with the drying. It cannot soak up water like a towel, because it cannot be wetted. Hence it can do no drying. But since evaporation increases with the temperature, hot air may promote the process by heating the objects to be dried. It may thus act as a heater, but not as a drier.

Evaporation, as we have seen, results from the livelier molecules shooting out of a liquid. But some of them shoot back again, and the rate at which they do so depends upon how many are on hand. If none are on hand, as when a liquid is first introduced into a vacuum, the rate of evaporation is then a maximum, and is determined only by the temperature. But as evaporation proceeds—the liquid being in a closed container kept at constant temperature—the density of the vapor increases, the number of molecules shooting back increases, and the net rate of evaporation *decreases*, until, when the vapor reaches the saturation density corresponding to the temperature, the net evaporation ceases. Hence the "dampness" of an environment, which is the inverse of its drying power, as measured by the rate of evaporation, increases as the vapor density increases, and reaches a maximum when the vapor is saturated. At any previous stage, the degree of dampness is measured by the quantity of vapor present in proportion to that required for saturation. This ratio is called the *relative humidity*, or simply the humidity. It is zero when no water vapor is present, 100 per cent when the vapor is saturated, 50 per cent when the vapor density is half that required for saturation at the given temperature, and so on.

In the calculations, we have paid no attention to the amount of air present, nor to the amounts of any other gases or vapors that might have been present. The only quantities used in reckoning the humidity were the amount of *water* vapor present, and the amount required for saturation at the given temperature. The air, other gases, or even other vapors that might be present, take no part in the drying process.

According to Boyle's law, the density of a gas is proportional to its pressure. This is also very nearly true for water vapor under the conditions we are considering. Now since the saturation pressure increases with the temperature, the values always being given by the Regnault steam line, it follows that larger·and larger quantities of water vapor will be required for saturation, that is, for 100 per cent humidity, as the temperature rises. And the same will be true for every other degree of humidity, except 0 per cent. The same amount of vapor present will therefore produce very different degrees of humidity according to the temperature. For instance, suppose that at a temperature of 66 degrees Fahrenheit the water vapor present is saturated. The humidity is then 100 per cent. In every cubic foot there is 0.001 pound of the vapor. Let the temperature now be raised to 102 degrees. The humidity drops to $33\frac{1}{3}$ per cent, for at this temperature 0.003 pounds of vapor per cubic foot are required for saturation, and only 0.001 pound is present. Heating therefore reduces the humidity, even though the amount of water vapor present remains the same.

When the density of a vapor is below that of saturation, the vapor is superheated. The vapor in the air, then, that causes all our so-called dampness is superheated steam. It becomes at most saturated steam when the humidity reaches 100 per cent. But the reader will know full well by now that these terms are not necessarily associated with high temperatures. Steam may be saturated and even superheated at temperatures far below the freezing point.

Suppose that into this environment at 102 degrees and $33\frac{1}{3}$ per cent humidity we introduce a wet thermometer. The temperature of the latter will fall because of the evaporation of the water. But it cannot fall below 66 degrees, for at that temperature, as we saw above, the vapor is saturated, and evaporation ceases. If we introduce an object that is colder than 66 degrees, dew will condense upon it. Sixty-six degrees is therefore the *dew point* for these conditions. Having determined it in this way, we have only to look up in the steam tables the saturation densities corresponding to the dew point, and to the air temperature, respectively, and their ratio will be the relative humidity, as given above.

At low temperatures, an extremely small amount of water

vapor suffices for saturation. At o degree Fahrenheit the saturation density is only 0.0003 pounds per cubic foot. A small room, ten by twelve, and eight and one-half feet high, or of about one thousand cubic feet capacity, would contain 1293 ounces of air, but only 1.1 ounces of water vapor. Yet the humidity would be 100 per cent. If this room were heated to 70 degrees, the humidity would drop to 6 per cent, which is very dry. To bring the vapor again to saturation at the increased temperature would require the addition and vaporization of a whole pound—about a pint—of water. That is why the air in our heated houses is always so dry in winter, even if it is quite damp outside. Conversely, when air is artificially cooled, the humidity increases, and unless some of the water vapor is removed, the air feels uncomfortably clammy.

People sometimes find it difficult to understand how there can be "moisture" in the air, when the temperature is below freezing. They think that it should all freeze up. And so it would if this "moisture" were in the form of water globules. But it is not. It is in the form of water *vapor*, which is a gas. A liquid can form only when the molecules are brought close together. In a gas they are far apart. There is hence no difficulty in cooling water vapor far below the freezing point, and still having it a gas, so long as we keep the molecules far apart. That is, we must keep the density low; we must get down under the Regnault frost line of Figure 25. This means that very little water vapor can be present at these low temperatures, for as soon as the density rises to a value on the frost line, the humidity becomes 100 per cent and the vapor condenses, not to water, however, but to frost or snow.

In all of this we have made no mention of any part played by the air. It has been entirely absent from our considerations, and might just as well have been physically absent also. The air does, however, play the part of establishing and maintaining the temperature. When a liquid evaporates, it is cooled. Conversely the vapor is warmed. The air, being of intermediate temperature, cools the vapor and warms the liquid. It thus restores to the liquid the heat it loses, and keeps up the rate of evaporation. Hence the air acts as a temperature equalizer. Other than that, it can only hinder evaporation by its molecules getting in the way of those shooting out of the

liquid, deflecting some of them back, and so preventing the vapor from diffusing away from the liquid as fast as it otherwise would. But this effect is very slight, as we shall now show.

John Dalton, the discoverer of the atomic weights, deduced as a consequence of the theory of perfect gases, that when several such gases are introduced into a closed container, each expands and fills the whole volume uniformly; and each exerts on the walls of the container a pressure which is exactly the same as it would have exerted had the others been absent. The only way the different gases affect one another is that their association constrains all to assume the same temperature. The pressure of each gas is then proportional to its density, that is, to the amount of it by weight that is present, and the total pressure on the container is the sum of the pressures exerted by the separate gases. This is called the law of *partial pressures*. One consequence is that a small sample of the mixture taken anywhere always shows the same composition.

Now these deductions of course apply only to perfect gases, whose molecules are infinitesimal or of practically no size. Such a gas may fill a volume by its pressure, and yet occupy none of its space. Hence when another gas is introduced, it finds the space still wholly empty. It is not surprising, then, that several perfect gases should be totally unaware of one another's presence, and act independently. There is nothing to them anyway. But real gases are composed of molecules of finite size. Hence they might be expected not to follow Dalton's law exactly. However, Regnault tested the matter experimentally with great care, and found that real gases and even vapors when not too dense obeyed the law very closely. Under ordinary circumstances, then, even real gases are nearly all space. Their molecules must be very small and far apart.

A further confirmation is afforded by the fact that chemical analyses of air show that the composition of the atmosphere is substantially the same all over the globe. This means that each of the component gases is thoroughly diffused. The only component that varies considerably is water vapor. This is constantly being renewed by evaporation and removed by condensation, and these processes vary considerably from place to place and from time to time, as our variable weather attests. However, the water vapor content seldom exceeds one

per cent of the whole, and all of it is confined to within a few miles of the earth. The upper strata are quite dry.

As a result of these facts, the presence of air or of other gases above a liquid can have but little restraining effect upon evaporation. The pressure of a gas on the surface of a liquid does indeed affect the boiling point, because, for a bubble of vapor to form in the interior of the liquid, it must push the liquid away against the opposing pressure, which is substantially that of the gas pressing upon its surface. But evaporation takes place molecule by molecule. When air is at a pressure of one atmosphere and 32 degrees Fahrenheit, only about one five-thousandth part of its volume is occupied by molecules. Hence the molecules of an evaporating liquid shoot into this space almost as freely, and diffuse through it almost as readily, as though there were nothing there. A liquid exposed to the air therefore evaporates nearly as rapidly as in a vacuum.

XIV

CONVECTION AND CONDUCTION

IMMEDIATELY above a hot body, such as a stove, we find a continual stream of warm air ascending. The air in contact with the stove is heated and expands, and becoming thus less dense than the surrounding air, it rises. Cold air is drawn up from below to replace the hot air, and so a continual stream is maintained. This process is called *convection*. It maintains the draught in our fireplaces and chimneys, the ebullition of boiling liquids, the circulation of cooling water in an automobile when there is no pump, etc. Convection carries away great quantities of heat. Moderately hot bodies exposed to the air cool more by this means than by any other.

The ancients were much impressed by the upward leaping of flames. They supposed fire to be one of the four elements, and that to rise was inherent in its nature. Hence the heavens were its natural abode, and all celestial bodies were of a fiery nature. Even Bacon reëchoed this view when, in his *Novum Organum*, he pronounced heat to be an expansive upward motion.

But a flame is only a gas heated to visibility, or containing incandescent carbon particles. It rises for the same reason that any other hot gas rises. It is, in short, a visible convection current, unusually strong, because of the high temperature. But the flame shows only a small part of the whole affair. If we place a lighted candle in the beam of a projection lantern and cast its shadow on a screen, the appearance shown in Figure 40 is produced. The flame itself occupies only the central part of a huge commotion, which looks like a much magnified flame that envelops not only the wick but a good part of the candle as well. This is simply a further portion of the

convection current, now rendered visible because it refracts the light differently than the surrounding air does.

By convection, heat is borne away by the steaming of the heated matter itself. It is possible only in a mobile fluid. By *conduction*, heat is conveyed from one part to another of a body without any progressive motion of its parts. It is handed on, so to speak, from molecule to molecule, and spreads like bad news in a crowd.

If a small part of a large body is heated, the molecules in this part are thermally agitated. Knocking against the surrounding molecules, they communicate their agitation to these, these

FIG. 40—THE SHADOW OF A FLAME

to others, and so on. The commotion, being thus distributed always among larger and larger groups, weakens as it spreads. The process is slow, and is much like the diffusion of a dissolved substance throughout a solvent. If only a limited amount of heat is communicated, it finally becomes evenly distributed throughout the body. The temperature becomes uniform. If heat is continually supplied, until the temperature of the body rises above that of the surroundings, the molecules at the surface communicate their excess agitation to the neighboring molecules of the air, so that heat escapes from all parts of the surface of the body. Thus a continuous flow of heat into and out of the body is maintained.

Heat, indeed, can be made to flow along a metallic bar much like water through a pipe. The longer and thinner the bar, the more difficult the passage, just as in the case of a water pipe. For this reason, the handles of our pots and pans are often made of coiled wire, instead of a solid piece. The path that the heat must tread is then long and narrow, and the surface from which it can escape is much increased. But the material of which the bar is composed also makes a difference. Some substances are good conductors, others are poor. Some are so bad that we call them nonconductors or insulators, but there are no perfect insulators.

The metals in general are good heat conductors, the nonmetals poor ones. If the pure metals are arranged in the order of their heat conductivities, this will also be the order of their electrical conductivities. There is a close connection between the two. The heat conductivities of a number of common substances are given in the table below in terms of silver = 1000. Mercury is among the poorest metallic heat conductors, with a conductivity one-fiftieth that of silver. The nonmetals range from one two-hundredth that of silver for ice to 1/20,000th for air.

A number of popular illusions have arisen from a lack of understanding of the rôle played by conductivity. If several objects are placed in a constant temperature enclosure, they will all finally come to the same temperature, that of the enclosure. But to the senses they will seem to be of very different temperatures. If the enclosure was cold, a poor conductor like wool will not feel especially cold. A better conductor like stone will feel decidedly cold, while any metal will seem bitingly cold. Conversely, if the enclosure was hot the wool will feel but slightly warm; wood, glass, and porcelain moderately hot; but any metal blisteringly hot. Doubtless from such experiences as these arose the notion that some bodies are naturally cold, others naturally warm. "Stone cold" is still a common expression, as though stone were always cold. And Bacon in his *Organum* listed wool and "all shaggy substances" as naturally warm. The illusion is due to the fact pointed out by Tait, that our sensations of hot and cold do not directly depend upon the temperatures of bodies, but upon the *rate* at which heat is conveyed to or from the skin. A good conductor when cold abstracts heat from the hand faster, and

therefore seêms colder, than a poor conductor does, even though
both have the same temperature.   Conversely the good con-
ductor when hot gives up its heat faster, and therefore seems
hotter than the poor one.   Also, as we shall see presently, the
closeness of the contact which the substance makes with the
skin affects the rate at which heat passes from one to the other.
All "shaggy substances" make poor contact.

It may surprise some to learn that water is a poor conductor
of heat, being about 1/770th as good as silver, and only three

RELATIVE CONDUCTIVITIES

Good Conductors

Silver	1000
Copper	940
Aluminum	520
Zinc	270
Tin	159
Iron	155
Lead	85
Mercury	20

Poor Conductors

Ice	5
Glass	1.3-2.5
Porcelain	2.5
Water	1.3
Cotton	0.56
Cardboard	0.5
Hydrogen	0.33
Flannel	0.23
Cork	0.13
Felt	0.09
Cotton wool	0.05
Air	0.05

times better than cotton, as may be seen from the table.   The
rapid cooling that can be obtained with water is due to con-
vection, not to conduction, and to good contact, as will appear
presently.   Pure water is also a very poor conductor of elec-
tricity.   All the liquids are poor conductors of heat, and do not
differ much in their conductivities from water   The conduc-
tivity of a liquid is difficult to measure, because it is hard to
prevent convection currents.   These are minimized by heating
the liquid at the top.

The poorest conductors of all are the gases. They are still more difficult to measure, not only on account of convection, but because most of the heat is transported directly across them by radiation. Hydrogen and helium are much higher in conductivity than the rest, which are all about the same as air.

One of the best heat insulators is a layer of air, as in the space between double walls. But convection currents must be prevented by filling the space with some loose material like feather stone. The conductivity of cotton by our table is 0.56, but that of cotton wool is 0.05, or about the same as for air. Hence it is the entrapped air that does all the insulating, not the cotton. The latter serves only to prevent air circulation. And because the conductivity of the cotton itself is higher, we must use as little of it as possible. It must not be packed tightly, but loosely. Similarly fur, felt, and all other "shaggy substances" owe their "warmth" to the entrapped and stagnant air. All heat insulating materials must be light, loose, and porous, in short, contain as little matter as possible.

If the pressure of a gas is very much reduced, its conductivity also falls. A perfect vacuum would be a perfect nonconductor, for there would be no matter present to effect the conduction. We cannot produce a perfect vacuum, but we can come quite near to it.

FIG. 41—THE DEWAR
VACUUM FLASK

The low conductivity of a near vacuum is applied in the Dewar vacuum flask. This is a double walled glass vessel as shown in Figure 41, the space between the double walls being exhausted of air. Convection and conduction are almost wholly absent. A small amount of heat may be conducted up the inner wall and down the outer. But this is a long, narrow, and difficult path, for the glass is thin and a poor conductor. Direct radiation takes place from the inner to the outer wall, and from thence to the air, but this is minimized by silvering the walls, so that some of the radiation is reflected back. This flask was originally invented in 1891 for experiments on liquid air, but is now embodied in the familiar thermos bottle.

Electric light bulbs were originally exhausted because the

carbon filament was combustible. But the practice is still continued with the modern metallic filaments, because loss of heat by convection and conduction is thereby much reduced. Since all heat losses must be made good by the electric current, this enables the filament temperature to be maintained with less current, which means a more efficient lamp.

One consequence of the low conductivity of a gas is a phenomenon known as the spheroidal state. If a drop of water falls on a moderately hot stove, it spreads out and quickly evaporates. But if the stove is very hot, the water gathers up into a little ball, which runs shimmering and spluttering about, and evaporates much more slowly. This is the spheroidal state. The hot stove causes such a rapid evaporation at the first instant of contact that the steam blowing downward pushes the drop up out of contact with the stove, and thereafter the drop rests on a cushion of its own steam. This being a poor conductor of heat prevents further rapid transfer of heat to the drop. The space between the drop and the stove can be seen with an arrangement like that of Figure 42. The eye is brought

FIG. 42—THE SPHEROIDAL STATE

to the level of the plate, and one looks at a bright light beyond.

Liquid air has a temperature of − 320 degrees Fahrenheit. Compared with that, the hand is a pretty hot stove. Consequently a drop of liquid air taken on the hand assumes the spheroidal state, and if not allowed to sit in one place too long, will produce no painful impression. Frozen mercury at − 38 degrees Fahrenheit, on the contrary, will produce a severe and painful burn. One can also dip his hands, if they are moist, into molten iron without injury. Here it is the steam evaporated from the hand that forms the insulating layer. Robert Houdin, the famous French magician, had the courage to try this experiment, although his hands of course were invaluable to him in his profession. It is not, however, an experiment to be recommended.

When one end of a conducting bar, which is heavily insulated as shown in Figure 43, is kept at a constant high temperature, and the other at a constant low temperature, there is a steady flow of heat through the bar; and if the bar is uniform, there is also a steady drop in temperature from the high to the low end, as shown by the dotted line connecting the tops of the mercury columns of the thermometers. The slope of this line, which is given by the total drop in temperature divided by *AB*, is called the *temperature gradient*. It is analogous to the slope of a hill down which water is running. In fact we have here a heat pipe, analogous to a water pipe connecting two reservoirs in
FIG. 43— THE TEMPERATURE GRADIENT

which the water stands at different levels, as in Figure 44. If the levels are kept constant, by pouring water into the one tank, and drawing it off from the other, as fast as the water flows between them, the flow will be steady. And if the pipe is uniform, there will be a steady drop in pressure or *head* along the pipe as shown by the water levels in the open vertical tubes inserted at intervals along the pipe.

Finally, we have the same thing in electricity. When the two ends of a uniform wire are kept at a constant difference of electrical pressure or potential (measured in volts), there is a steady flow of electricity along the wire, and a uniform drop in potential from the high to the low end—a potential gradient.

In all three cases the steadiness of flow depends upon the constancy of the end conditions; the steepness of the gradient depends upon the *resistance* of the bar, pipe, or wire, and the

latter upon its cross-section and specific conductivity; the uniformity of the gradient depends upon the uniformity of the bar, pipe, or wire. Wherever there is a constriction, there will be a greater resistance, and the gradient will be steeper. A more rapid fall in temperature, height, or potential will be required to force the heat, water, or electricity through this difficult place.

Especially difficult places occur where two different pieces or bodies come into contact. In electricity we call it contact resistance. Everybody knows that the contact must be good. The abutting surfaces must be large, and they must be clamped, screwed, or otherwise tightly pressed together. If the contact is
FIG. 44 - PRESSURE GRADIENT IN A WATER PIPE

poor, there will be a large drop in potential or temperature at the place, as shown in Figure 45. Solids make poor contact because their surfaces are always rough, as exaggeratedly indicated in the figure, even when they seem quite smooth. Liquids make good contacts with each other and with solids, because they flow into every depression. Hence soldered or welded joints are good, both in electricity and in heat.

A gas and a solid make exceedingly poor contact, for the reason that a gas is mostly space. At any given instant only one three-hundredth to one five-hundredth part of the surface of the solid will be in contact with the gaseous molecules and delivering heat to them by conduction. There is hence great difficulty in transferring heat from a solid to a gas and *vice versa*, especially if it must be done quickly. Large contact surfaces and a great difference in temperature are required. This circumstance has caused the failure of every hot air engine that has ever been devised. It is for this reason that the

temperature of a kettle on the stove is much nearer to that of the water it contains, than to that of the fire. The heat of the latter can pass to the kettle only at the expense of a great drop in temperature, 1000 degrees or more. In passing through the metal of the kettle there is almost no drop, for it is a good conductor. In passing from the kettle to the water there is again but little drop, because the contact is excellent. However hot the fire, the kettle is hence at nearly the same temperature as the water. This fact can be strikingly demonstrated by the
FIG. 45—CONTACT RESISTANCE

little experiment pictured in Figure 46. Water can be boiled in a paper box as shown without even charring the paper. If, however, the flames pass up around the sides of the box, they will burn the paper above the water's edge.

It is for these same reasons that a swimmer gets cold, even if the water is as warm as the air. The water makes close contact with his body and rapidly withdraws heat from it, while the air makes poor contact. If a red-hot poker is exposed to the air, it cools slowly. But if it is plunged into water, it quenches immediately. Liquids are therefore much more effective coolers than gases such as air, not only because of their higher thermal capacities, as already pointed out, but also because of far less contact resistance.

Let us now try another experiment with the heat pipe of Figure 43. Instead of subjecting the two ends to constant temperatures, let us subject the end A to a temperature that alternately rises and falls above and below that to which the end B is subjected, and which is kept constant. Because it takes time for heat to travel, it is evident that at any point along the rod the temperature will not begin to rise until some time after it has started to do so at A. The more distant the point, the greater will be the delay. But if there is no leakage of heat

along the way, each point will eventually execute the same alternations of temperature that were impressed at *A*. In short, a *temperature wave* will travel along the rod.

If at some point on the rod, the temperature does not begin to rise until at *A* it has already reached a maximum and descended again to the mean, these two points are said to be in *opposite phase*. For the temperature at the one is rising while that at the other is falling, and *vice versa*. The distance along the bar between the two points is then half a wave length. A
FIG. 46—BOILING WATER IN A PAPER BOX

point at double this distance will be again *in phase* or *in step* with *A*, and this distance will be one wave length.

Since the temperature at *B* rises and falls alternately above and below that of its surroundings, heat will flow out of and into the rod at this point. Instead of a continuous flow, we shall have a back and forth movement of heat in the rod—an alternating current of heat. Thus no heat is permanently transferred from one end to the other. The wave alone is propagated in a definite direction.

We have supposed perfect insulation, but this is never possible. Moreover, there will always be loss from radiation.

Heat will therefore leak out all along the way, and the waves as they advance will diminish in amplitude. Short waves die out more rapidly than long ones. Very short waves have so great a tendency to spread in all directions, that it is impossible to force them very far in any one direction. They die out almost immediately. Since heat travels slowly and is difficult to insulate, only very slow alternations can be transmitted to any considerable distance.

Exactly similar relations hold for electricity. But electricity travels fast, and is easy to insulate. Hence much higher frequencies can be transmitted along a wire, and to much greater distances. But here, too, the higher frequencies die out more rapidly, and a limit in wire transmission is set by the tendency of the short waves to radiate in all directions away from the wire. This tendency of course is made use of in wireless telegraphy.

We are perhaps accustomed to think that these relations apply primarily and particularly to electricity. But they were all discovered and worked out for heat by Fourier in 1822, long before any one dreamed of applying them to electricity.

These temperature waves are exemplified by many common occurrences. Every day at noon the sun reaches its highest point in the heavens, and is then sending us the maximum amount of heat. But the hottest part of the day occurs between two and four in the afternoon, and the coldest part of the night between two and four in the morning. There is hence a lag of from two to four hours in the diurnal temperature wave in the atmosphere near the earth's surface. This is because the sun's heat penetrates the ground a short distance, and warms the objects all about. These take time to cool off, and in so doing continue to warm the air for a time after the sun's rays have begun to decline.

Inside a house there is a further lag on account of the time required for the heat to penetrate the walls, and to be re-emitted by them. Indoors it may still be hot in the evening while outside it is already cool, or cold in the morning when it is already warm outside. If the walls are very thick, as at the base of the Washington Monument, it may be cold in the daytime and warm at night, a lag of twelve hours.

We have also a seasonal wave. The days are longest and we receive most heat in June. They are shortest and we receive

the least heat in December. But the hottest month is August and the coldest is February. There is here a lag of two months. This is mostly due to the heat that penetrates the ground during the warming, and is slowly given out during the cooling.

We can follow these waves into the ground by placing thermometers at different depths and reading them at intervals. In this way it has been found that the short diurnal variation dies out in from three to four feet; but the long seasonal wave can be followed to a depth of fifty feet or more. The amplitude diminishes rapidly at first and then more slowly as shown in Figure 47. Only a few feet down the seasonal wave has so far diminished that the freezing point is never reached. Pipes laid underground do not freeze, and underground chambers
FIG. 47—THE UNDERGROUND SEASONAL TEMPERATURE WAVE

maintain a nearly constant temperature the year round. There is, of course, also a progressive increase in lag. At twenty-five feet, the wave is already six months in arrears, so that at this depth it is warm in winter and cool in summer. The whole variation, however, is then only one-twenty-third of its value at the surface. At fifty feet, the wave is a year behind, and its

amplitude one-five-hundredth of that at the surface—practically no variation at all.

One hot summer's day, when the author was on a hiking trip in Canada, the party came to a spring whose water was extraordinarily cold.   The guide told the party that in winter this water was warm.   Now this may have been only an effect of contrast; but it may also have been true.   If the water came from a depth of twenty-five feet, it would come from a region where the seasons are reversed.   However, with a variation at the surface of 92 degrees between summer and winter, there would be at this depth a variation of only 4 degrees.   This would scarcely be perceptible to the unaided senses, especially with an interval of six months between the observations to be compared.

XV

RADIATION

IF one brings his hand near a hot object, its heat can be felt before the object is touched. Evidently heat is transmitted across the space between the object and the hand. That this can take place without the intervention of matter, is proved by the fact that heat comes to us from the sun across ninety-three million miles of vacuum. It reaches us also from the far more distant stars. In fact, any matter whatsoever in the path of this radiant heat obstructs its passage, and may stop it altogether; for all bodies absorb it more or less, and only a complete vacuum is perfectly transparent to it. By conduction and convection the transfer of heat is effected *by means of matter*, and heat can be transferred in this way only as far as matter extends or can itself be transported. By the process of radiation, however, heat is divorced from its association with matter, and can travel in this way as far as empty space extends, which is to say, indefinitely.

When a total eclipse of the sun occurs, the heat and light received are both cut off at the same instant. Hence both travel in a vacuum with the same speed. Heat rays like light rays travel in straight lines, as is proved by the heat shadows cast by heat opaque objects. Both forms of radiation diminish in intensity as the square of the distance increases. Heat rays can be reflected, refracted, and brought to a focus as by means of a burning glass. In all of these ways they are completely analogous to light rays.

The mechanics of radiation, of its propagation, and absorption, are not yet fully understood. We shall not here discuss the rival wave and quantum theories, the existence or nonexistence of an ether, which are very large questions, but shall confine ourselves to the essential facts, which are independent of any theory.

When a body radiates it is cooled.   The body which receives
and absorbs the radiation is heated.   The transaction there-
fore represents a transfer of energy.   The ray is born of some
kind of agitation or oscillation.   In the most general sense an
oscillation is merely a repeated series of events that takes place
at a definite locality.   The number of times per second that the
series is repeated, is called the *frequency*.   When a ray is ab-
sorbed, it produces in the absorbing body an agitation or
oscillation which also has a frequency.   Hence the ray itself
must embody a frequency.   Experiment shows that with every
ray, at least on its arrival, is associated a very definite frequency,
and that there is a considerable range of these.

If two rays striking at the same point are such that they
produce equal oscillations in opposite phase, they annul each
other's effect.   This is *interference*.   We can obtain it with
sound, adding sound to sound to produce silence.   We can
obtain it with light, adding light to light to produce darkness.
We can obtain it with heat rays, adding heat to heat to produce
absence of heat.

Sound, light, and heat rays will also bend to some extent
around the edges of obstacles.   This is called *diffraction*.   It is
also a frequency effect, for it is large when the frequency is low,
and small when the frequency is high.   It is very large for
sound.   Thus we can hear the shout of a man who is behind a
house, but we cannot see the fire he has built nor feel its warmth.
Nevertheless, by very delicate instruments we can find near the
edge of the shadow both light and heat rays that have bent
slightly into the shadow.   Sound, therefore, has low frequency;
light and heat rays have very high frequencies.

Light and heat we have seen travel at the same speed.   The
speed is very high, 186,000 miles per second.   Sound travels
only eleven hundred feet per second.   Sound also requires the
presence of air or of some other material substance for its pro-
pagation, whereas light and heat rays traverse a vacuum
unhindered.   There is yet a third difference.   If we pass light
or heat rays through certain forms of apparatus, we find that it
makes a difference whether a certain part of this apparatus
(which may be a crystal) is rotated on an axis parallel with the
rays, say, from a vertical to a horizontal position.   Interference
will occur in the one position and not in the other.   This effect
is called *polarization*.   It does not occur with sound.

So far, however, we have uncovered no physical distinction between heat and light rays. There remains but one possibility—a difference of frequency. In fact, heat rays are found to have a lower frequency than light rays. This is proved by their greater diffraction or bending into the shadow, or by their less refraction or bending when they enter obliquely a denser medium. When, for example, the sun's rays are brought to a focus by a burning glass, the hottest spot will be found slightly farther from the glass than the brightest spot, showing' the less convergence or bending of the heat rays by the lens. But a more satisfactory demonstration is given by a slit and prism arranged as in Figure 48.
FIG. 48—SPECTRUM OF SUNLIGHT

The white light of the sun contains a number of frequencies. When the light passing the slit falls upon the prism, the rays are differently refracted or bent according to their frequencies, the high frequency rays being bent the more. The rays are thus sorted out according to their frequencies, which to the eye is according to their colors. The white light is thus drawn out

into the rainbow band we call the spectrum. Violet light is refracted the most and therefore has the highest frequency. It stands at the end of the spectrum nearer the base of the prism, the right-hand end in the figure. Red is refracted the least, and therefore has the lowest frequency. It stands at the other end of the spectrum. The other colors fall in between. If now we place a series of sensitive thermometers along the spectrum, and some to the right, and some to the left of it, as was first done by William Herschel in 1800, we shall find that they all rise in temperature. But those in the visible part of the spectrum rise very little, those to the right still less. Those to the left, however, show a very considerable rise in temperature. Here, then, in the low frequency region, in the *infra-red*, there are invisible rays that have great heating power. But *all* the rays show *some* heating effect, even those in the *ultra-violet* region to the right. All, then, are really heat rays. Light rays are simply those heat rays that happen to affect the optic nerve of the human being. Nevertheless, for distinction and convenience, and because most of the heat is there, we agree to call the infra-red the real heat spectrum. The extent of the infra-red is very much greater than that of the visible spectrum. The frequency of violet light is about eight hundred million million per second, that of red light is half of this. The infrared begins, therefore, at a frequency of four hundred million million, and it has been followed down to a frequency of about two million million. In terms of inverse frequencies, which on the wave theory would be wave lengths, the infra-red is two hundred times as long as the visible spectrum. If the latter were one inch in length, the former would be over sixteen feet long. Even this is not the end, for the infra-red merges into the electric spectrum.

The radiation that falls upon a body is partly absorbed, partly transmitted, and partly reflected. If a large proportion is absorbed, the body is *opaque*. If a large proportion is transmitted, the body is *transparent*. A body is not heated by the radiation it transmits or reflects, but only by what it absorbs. Thus, the sunlight that streams through the windowpanes does not heat the glass, but heats the objects in the room that catch and absorb it.

We usually think of bodies as opaque or transparent, according to whether they stop or transmit light. But bodies that are

transparent to light are not necessarily transparent to heat rays or *vice versa*. Glass is transparent to both, but water is more opaque to heat. It is for this reason that a water cell is interposed in a projection lantern between the arc and the film to protect the latter. The light rays pass freely, but the heat rays are largely intercepted, and may even bring the water to boil. Fluor spar and rock salt, though opaque to light, are transparent to heat, for which reason prisms and lenses made of these substances are much used in experiments on radiant heat. One must remember also that the infra-red spectrum covers a very large range of frequencies. A body may be transparent to one range and opaque to another, just as is the case with light rays, from which the colours of objects are due. Glass, for example, though transparent to the higher frequency heat rays, is quite opaque to the low frequency ones. Rock salt on the other hand is transparent to the very low frequencies, and is extremely useful on this account.

Many years ago Benjamin Franklin laid pieces of cloth of various colors on snow exposed to the sun, and noted how far each sank by the melting of the snow beneath. The darker ones sank the farther, from which he concluded that they were the better absorbers of heat, and recommended that dark colors be worn in winter and light ones in summer. This conclusion is not entirely justified, however. A black substance absorbs more *light* than a white one, but this tells us nothing about its absorption of *heat.* Tyndall, for example, showed that alum, which is white, is a much better heat absorber than iodine, which is dark; and black amorphous phosphorus is a poor absorber of heat, while sugar is a good one.

Low frequency radiation is associated with low temperature heat, and high frequency with high temperature heat. If we gradually heat a refractory substance, its radiations are at first of very low frequency. But as the heating proceeds, radiations of higher and higher frequencies are added until the body begins to glow with a dull red color. We have at this point reached the low frequency end of the visible spectrum. If the temperature is still further increased, the glow brightens, its color changes to orange, to yellow, and finally to a dazzling white. The whole visible spectrum is now present in addition to the infra-red. It is because the higher the temperature, the greater is the proportion of visible rays to the total heat emitted,

that electric lamp filaments are run at the very highest temperatures consistent with a reasonable life of the lamp. The light is then also whiter and more nearly like daylight.

Since all light rays produce heating effect, light entirely without heat is impossible. But the heating effect of the visible rays, especially of those toward the violet end of the spectrum, is exceedingly small. Any means by which these rays could be excited, without at the same time arousing the infra-red, would give a close approximation to light without heat. We have such means in the neon light, in phosphorescence, and in other such phenomena.

The fact that glass is transparent to high frequency heat rays and opaque to low frequency ones, makes it possible to use it as a sort of heat trap. This is the principle of the hothouse. The sunlight enters with its high frequency heat rays and warms the ground and the objects in the hothouse. These re-radiate the heat, but it is now low temperature heat, and the rays are of low frequency. These are stopped by the glass, and so the sun's heat is trapped.

It was suggested by Fourier about 1800 that the earth's atmosphere may similarly act as a heat trap, and that this would account for the comparatively mild and equable climate of our planet in contrast to the violent alternations of temperature that take place on the airless moon. These violent alternations, by the way, were more or less a matter of conjecture in those days, but they have recently been confirmed by measurements made at Mount Wilson, California. During the lunar night, the temperature descends to that of liquid air; during the day, it rises above that of boiling water.

This theory of Fourier's is appropriately called the hothouse theory. It was carefully tested by Tyndall, who in 1859 began a series of measurements of the transparency of gases and vapors to the low temperature radiations of a cube of boiling water. He found, indeed, that these substances were more opaque to the low than to the high frequency radiations, so that there is a hothouse effect. But he also found that some constituents of the atmosphere are much more effective in this respect than others. Water vapor he found to be seventy times, and carbon dioxide ninety times more opaque to the low frequency rays, than dry air. The hothouse effect of the atmosphere therefore depends largely upon the percentages of these con-

stituents present. This doubtless accounts for the more equable climate of humid than of dry regions.

Arrhenius, in his *Worlds in the Making* (1908), drew some rather remarkable conclusions from the high opacity of carbon dioxide. He believes that the warm and equable climate that prevailed all over the earth at the time of the carboniferous age, when coal was laid down in Alaska, Spitzbergen, and even on the Antarctic Continent, was due to the high percentage of carbon dioxide then in the air. He further believes that nearly all of the oxygen now in our atmosphere was produced by the stupendous vegetation of that age, which decomposed the carbon dioxide, depositing the carbon in the ground and liberating the oxygen. Hence, when all our coal is burnt, so too will nearly all the oxygen in the air be exhausted. However, by this replacement of the carbon dioxide in the atmosphere, the earth's climate should again become mild. This may compensate to some extent for the depletion of our coal and oxygen, provided that we can meanwhile develop lung capacity adapted to the stuffy atmosphere. At the rate that our factory chimneys are now pouring carbon dioxide into the air, Arrhenius thinks that a century or two should already make a noticeable difference in the climate. But if man is not ultimately to die of suffocation, or return to the primitive, it is obvious that he must find some other source of mechanical power for his industries than the burning of fuel.

Bodies that are transparent to heat rays are poor conductors of heat. One must not confuse transmission and conduction. All the metals are very opaque to heat rays, because they are good conductors of heat. If we wish to shield ourselves from the radiation of a fire, we should interpose a sheet of metal. Wood, glass, or any other poor conductor of equal thickness, would be much less effective. We have the same relations in electricity. Good conductors of electricity are opaque to electric waves, while insulators are transparent. A thin copper screen will stop radio waves completely, while thick stone or brick walls offer almost no hindrance. In fact the whole radio receiver is operated by the waves that are stopped by the antenna wire.

The rate at which a body emits heat depends upon the nature and extent of the surface, and its temperature. A rumpled or rough surface radiates better than a smooth one.

Hence we provide the cylinders of an air-cooled motor with many pallets and vanes, so as to get as much surface as possible. On the other hand, the calorimeters used in heat measurements are nickel plated and highly polished, so as to reduce the radiating surface. For the same reason the inner walls of the vacuum space of a thermos bottle are coated with quicksilver, since this reduces the radiation as well as reflecting some of it back.

But more than anything else the rate of radiation depends upon the surface temperature. Newton found that for a moderately warm body exposed to the air, the rate of cooling is proportional to the elevation of its temperature above that of the surroundings. This is called Newton's law of cooling. It can easily be verified by filling a flask with hot water, inserting a
FIG. 49—NEWTON'S COOLING CURVE

thermometer, and reading the latter at intervals. Then making a temperature-time plot, the curve shown in Figure 49 is obtained. At every point of this curve, the ratio of the drop in temperature per minute dt to the temperature *height* t of the point above the room temperature is a constant. The *rate* of cooling at every instant is therefore proportional to the temperature height. It is rapid at first, becomes slower and slower, and approaches the room temperature asymptotically. An infinite time would theoretically be required to cool completely to the room temperature.

If a waiter brings you a cup of black coffee, and you intend

to use sugar and cream, you should put them in at once, instead of waiting until you are ready to drink the coffee. This will lower the temperature at once, but the subsequent loss of heat by cooling will be less because of this lowered temperature, and the coffee will be hotter in the end than it would be if you had delayed putting in the sugar and cream.

Some of our housewives are of the opinion that tea will keep hot in a silver teapot longer than it will in a china one. This they prove to themselves by *feeling* of the pot, which they find after a lapse of time still feels quite hot, whereas the china pot does not. But, as pointed out in the preceding chapter, silver is an exceedingly good conductor of heat, whereas china is not. So even if both were at the same temperature, the silver pot would *feel* hotter. Furthermore, the good woman feels the *outside* of the pot. Now, because of its high conductivity, the outside of the silver pot will be nearly as hot as the tea within, while the outside of the china pot, because of its low conductivity, will be much cooler. Precisely because of its high *outside* temperature, the metal pot cools faster. The very fact that it *feels* hot, shows that it parts with its heat readily. A thermos bottle, even when filled with a boiling liquid, feels scarcely warm on the outside. It is because of this low surface temperature that it cools slowly. The whole temperature gradient is inside the bottle instead of outside. And you will not discover after an hour's time if the liquid within is still hot, by feeling the outside of the bottle.

The curve representing Newton's law of cooling is useful in many other ways. Mathematically it is a logarithmic or exponential curve. It is the plot of a geometrical against an arithmetical series. It is the relation between multiplying and adding. It represents the growth or decline of any quantity where the *rate* is always proportional to the amount on hand. Hence it represents the growth of capital when put out at compound interest, the increase of population according to the law of Malthus, the growth of any organism by the multiplication of its cells, It represents the rate of radium decay; it is the so-called logarithmic decrement of damped vibrations, especially applicable to radio waves. In Figure 1 (page 4) this same curve, turned a quarter turn to the right so that the asymptote becomes vertical, showed the relation between a sensation and its stimulus known as Weber's law. In Figure 47, the same

curve, reversed as in a mirror, showed the manner in which temperature waves die out as they penetrate underground. These are only a few of the many applications of this curve, which are found in such diverse fields as physics, economics, sociology, biology, and psychology.

Unfortunately this simple cooling law holds only for moderately warm bodies. Moreover, it is not a pure radiation law, for most of the heat is carried away by convection and some by conduction. If these are prevented or reduced to a very low figure, as by suspending the hot body in a vacuum, it is found that the rate of radiation increases much faster with the temperature than according to Newton's law. Stefan found empirically in 1879 that the rate of radiation is proportional to the fourth power of the absolute temperature of the radiating body, and Boltzman later deduced the same law from theoretical considerations. According to this law, if the absolute temperature of a body is doubled, it radiates sixteen times as fast. At moderate temperatures, then, radiation plays but little part. Most of the heat is carried away by convection and conduction. But at high temperatures it plays the dominant rôle, and in the case of the sun and the stars, which are entirely immersed in a vacuum, it plays the entire rôle. However, Newton's cooling law is sufficiently exact for many purposes, when the bodies concerned are only slightly warmer than their surroundings. It is much used to correct calorimeters and other heat apparatus for loss of heat during the experiment.

It may be noted that Newton's law states that the rate of cooling depends upon the *difference* between the temperature of the body and that of its surroundings, whereas Stefan's law states that the rate of radiation depends upon the absolute temperature of the radiating body alone. According to Stefan, then, a body is always radiating, even if its temperature is much below that of the surroundings. How is it, then, that a body does not cool itself right down to the absolute zero? The answer is given by Prévost's *theory of exchanges*. The cold body radiates to the surroundings, but the surroundings also radiate to the body, and much faster because of their higher temperature. Hence the body receives more heat than it loses. Its temperature rises, while that of the surroundings falls, until the two are equal. Both then radiate at the same rate.

Consider two bodies *A* and *B*, Figure 50, in an enclosure

whose walls are perfectly reflecting. Then all the radiation of each body falls eventually either upon itself or upon the other body, and both will finally assume the same temperature. Let us suppose that *A* was originally at a white heat, *B* at a red heat. Then after equalization both may be at a yellow heat. Are we to suppose, that now that the two are at the same temperature, they have ceased to radiate, and that if we could peek into the enclosure, as through a small hole, without disturbing the arrangements, we would see nothing? By no means! We would see two glowing yellow bodies. We are forced then to conclude that at equal temperatures bodies continue to radiate, and therefore that they radiate at all temperatures.

When a body is exposed to radiation, as to that of the sun, its temperature rises until the rate at which it loses heat, by re-radiation and other means, is equal to the rate at which it receives heat. Hence a thermometer set out in the sun will rise above the temperature of the surroundings; but the extent of this rise depends not only upon the intensity of the radiation, but upon the absorbing and reflecting power of the thermometer. It will be quite different with different instruments.

FIG. 50—THE THEORY OF EXCHANGES

Even the same instrument exposed to the same radiation will show a higher temperature, if the reflecting power of the bulb is diminished and its absorbing power increased, by simply blackening it. But the object of a weather thermometer is to indicate the air temperature. Hence it should be used in the shade, and furthermore the bulb should be protected even from such radiations as are present in the shade by a perforated metallic screen over it. Readings taken in the sun have no meaning, and there is no sense to assertions about how hot it is in the sun.

While the rate at which a body radiates depends only upon the nature and temperature of its surface, the rate at which heat can be brought up to the surface from the interior depends upon the conductivity of the body. If it is a poor conductor, heat can only be brought up slowly. Consequently, the surface

will be considerably cooler than the interior, and the rate of radiation will be low. A steep temperature gradient will be required to drive the heat to the surface. That is why a thermos bottle, though filled with hot liquid, is scarcely warm on the outside and cools very slowly.

The earth itself is a sort of thermos bottle. As we penetrate below the surface, we find a steady rise in temperature of about one degree Fahrenheit for every sixty feet. At this rate, the melting points of the rocks, even allowing for the elevation produced by pressure, would be exceeded at a depth of only one hundred miles, and at the earth's center the temperature would reach 350,000 degrees Fahrenheit, forty times that of the sun's surface. Hence it was formerly supposed that the earth's interior was molten. But in that case there would be tides in this fluid, like those in the ocean, only stronger. There are earth tides, but they are extremely minute. For these and other reasons, astronomers have come to the conclusion that the earth is solid throughout —except for isolated pockets where volcanoes occur—and very rigid. It is impossible, therefore, that the temperature gradient found near the surface should continue with undiminished steepness to the center. And there are other reasons why it cannot. The average density of the surface rocks is 3.5, that of the earth as a whole is 5.5. Hence the density at the center must be greater than at the surface, probably twice as great, which is the density of iron. And since the earth is magnetic, it is believed that the core *is* mostly iron. Hence as we descend, the materials grow heavier, their conductivity increases, and the temperature gradient must decrease. The interior is hot, but probably not above the melting point of iron at the pressure to which it is there subjected. Thus we have a hot, good conducting core, surrounded by a layer of poorly conducting material analogous to a thermos bottle.

In 1862 Lord Kelvin undertook to determine how long it had taken the earth to cool down from an originally completely molten condition. In his famous paper, "On the Secular Cooling of the Earth," he gave the time as probably one hundred million years; but on account of great uncertainties in the data, he set the rather wide limits of, not more than four hundred million nor less than twenty million years. The calculation was often repeated during the succeeding years, by

Kelvin himself and by others, and they came to favor strongly the lower limit. Tait even reduced it to ten million years. But all this greatly dissatisfied the geologists and biologists, who insistently demanded more time for their evolutionary processes. Besides they had their own methods of reckoning the age of the earth, from the rates of denudation, sedimentation, accumulation of salt in the ocean, etc., all of which gave much higher figures. The physicists looked upon these estimates rather contemptuously, and regarded their own method as the only exact and authoritative one. The discovery of radium in 1898, however, put an entirely different complexion upon the matter. This and other radioactive substances are continually giving off heat, and while they occur only in extremely minute quantities, yet in the whole crust there is enough of them to supply all the heat which comes up from the interior of the earth. The earth at present is apparently not cooling at all, and this balance has probably existed for a long time past. This is in accord with the geological evidence, which does not indicate a hotter and hotter earth as we go back in time, but a very long continuance of temperature conditions much like the present.

While radioactivity has thus invalidated all the old estimates based on secular cooling, it has fortunately provided a new method of measuring geologic time, perhaps more accurate than any other. Uranium disintegrates through a long series of intermediate products, including radium, to lead of a particular atomic weight. From the ratio of the amount of this sort of lead to the uranium in the igneous rocks in which they occur, the age of these rocks can be calculated. These estimates run to one thousand million years and more. Hence the claims of the geologists have been more than justified, and the physicists are now as generous with their allowances to time as they were previously niggardly, and everybody is happy.

CATALOG OF DOVER BOOKS

BOOKS EXPLAINING SCIENCE AND MATHEMATICS

THE COMMON SENSE OF THE EXACT SCIENCES, W. K. Clifford. Introduction by James Newman, edited by Karl Pearson. For 70 years this has been a guide to classical scientific and mathematical thought. Explains with unusual clarity basic concepts, such as extension of meaning of symbols, characteristics of surface boundaries, properties of plane figures, vectors, Cartesian method of determining position, etc. Long preface by Bertrand Russell. Bibliography of Clifford. Corrected, 130 diagrams redrawn. 249pp. 5⅜ x 8.
T61 Paperbound **$1.60**

SCIENCE THEORY AND MAN, Erwin Schrodinger. This is a complete and unabridged reissue of SCIENCE AND THE HUMAN TEMPERAMENT plus an additional essay· "What is an Elementary Particle?" Nobel Laureate Schrodinger discusses such topics as nature of scientific method, the nature of science, chance and determinism, science and society, conceptual models for physical entities, elementary particles and wave mechanics. Presentation is popular and may be followed by most people with little or no scientific training. "Fine practical preparation for a time when laws of nature, human institutions . . . are undergoing a critical examination without parallel," Waldemar Kaempffert, N. Y. TIMES. 192pp. 5⅛ x 8.
T428 Paperbound **$1.35**

PIONEERS OF SCIENCE, O. Lodge. Eminent scientist-expositor's authoritative, yet elementary survey of great scientific theories Concentrating on individuals Copernicus, Brahe, Kepler, Galileo, Descartes, Newton, Laplace, Herschel, Lord Kelvin, and other scientists the author presents their discoveries in historical order adding biographical material on each man and full, specific explanations of their achievements. The clear and complete treatment of the post-Newtonian astronomers is a feature seldom found in other books on the subject. Index. 120 illustrations xv + 404pp. 5⅜ x 8
T716 Paperbound **$1.50**

THE EVOLUTION OF SCIENTIFIC THOUGHT FROM NEWTON TO EINSTEIN, A. d'Abro. Einstein's special and general theories of relativity, with their historical implications, are analyzed in non-technical terms Excellent accounts of the contributions of Newton, Riemann, Weyl, Planck, Eddington, Maxwell, Lorentz and others are treated in terms of space and time, equations of electromagnetics, finiteness of the universe, methodology of science 21 diagrams. 482pp. 5⅜ x 8.
T2 Paperound **$2.00**

THE RISE OF THE NEW PHYSICS, A. d'Abro. A half-million word exposition, formerly titled THE DECLINE OF MECHANISM, for readers not versed in higher mathematics. The only thorough explanation, in everyday language, of the central core of modern mathematical physical theory, treating both classical and modern theoretical physics, and presenting in terms almost anyone can understand the equivalent of 5 years of study of mathematical physics. Scientifically impeccable coverage of mathematical-physical thought from the Newtonian system up through the electronic theories of Dirac and Heisenberg and Fermi's statistics. Combines both history and exposition, provides a broad yet unified and detailed view, with constant comparison of classical and modern views on phenomena and theories "A must for anyone doing serious study in the physical sciences," JOURNAL OF THE FRANKLIN INSTITUTE. "Extraordinary faculty   to explain ideas and theories of theoretical physics in the language of daily life." ISIS First part of set covers philosophy of science, drawing upon the practice of Newton, Maxwell, Poincare, Einstein, others, discussing modes of thought, experiment, interpretations of causality, etc. In the second part, 100 pages explain grammar and vocabulary of mathematics, with discussions of functions, groups, series, Fourier series, etc. The remainder is devoted to concrete, detailed coverage of both classical and quantum physics, explaining such topics as analytic mechanics, Hamilton's principle, wave theory of light, electromagnetic waves, groups of transformations, thermodynamics, phase rule, Brownian movement, kinetics, special relativity, Planck's original quantum theory, Bohr's atom, Zeeman effect, Broglie's wave mechanics, Heisenberg's uncertainty, Eigen-values, matrices, scores of other important topics Discoveries and theories are covered for such men as Alembert, Born, Cantor, Debye, Euler, Foucault, Galois, Gauss, Hadamard, Kelvin, Kepler, Laplace, Maxwell, Pauli, Rayleigh, Volterra, Weyl, Young, more than 180 others. Indexed. 97 illustrations. ix + 982pp. 5⅜ x 8.
T3 Volume 1, Paperbound **$2.00**
T4 Volume 2, Paperbound **$2.00**

CONCERNING THE NATURE OF THINGS, Sir William Bragg. Christmas lectures delivered at the Royal Society by Nobel laureate. Why a spinning ball travels in a curved track, how uranium is transmuted to lead, etc. Partial contents· atoms, gases, liquids, crystals, metals, etc. No scientific background needed, wonderful for intelligent child. 32pp of photos, 57 figures. xii + 232pp. 5⅜ x 8.
T31 Paperbound **$1.35**

THE UNIVERSE OF LIGHT, Sir William Bragg. No scientific training needed to read Nobel Prize winner's expansion of his Royal Institute Christmas Lectures Insight into nature of light, methods and philosophy of science. Explains lenses, reflection, color, resonance, polarization, x-rays, the spectrum, Newton's work with prisms, Huygens' with polarization, Crookes' with cathode ray, etc Leads into clear statement of 2 major historical theories of light, corpuscle and wave Dozens of experiments you can do. 199 illus., including 2 full-page color plates. 293pp. 5⅜ x 8.
S538 Paperbound **$1.85**

ANALYSIS & DESIGN OF EXPERIMENTS, H. B. Mann. Offers a method for grasping the analysis of variance and variance design within a short time. Partial contents: Chi-square distribution and analysis of variance distribution, matrices, quadratic forms, likelihood ration tests and tests of linear hypotheses, power of analysis, Galois fields, non-orthogonal data, interblock estimates, etc. 15pp. of useful tables. x + 195pp. 5 x 7⅜. **S180 Paperbound $1.45**

Numerical analysis, tables

PRACTICAL ANALYSIS, GRAPHICAL AND NUMERICAL METHODS, F. A. Willers. Translated by R. T. Beyer. Immensely practical handbook for engineers, showing how to interpolate, use various methods of numerical differentiation and integration, determine the roots of a single algebraic equation, system of linear equations, use empirical formulas, integrate differential equations, etc. Hundreds of shortcuts for arriving at numerical solutions. Special section on American calculating machines, by T. W. Simpson. 132 illustrations. 422pp. 5⅜ x 8.
S273 Paperbound $2.00

NUMERICAL SOLUTIONS OF DIFFERENTIAL EQUATIONS, H. Levy & E. A. Baggott. Comprehensive collection of methods for solving ordinary differential equations of first and higher order. All must pass 2 requirements: easy to grasp and practical, more rapid than school methods. Partial contents: graphical integration of differential equations, graphical methods for detailed solution. Numerical solution. Simultaneous equations and equations of 2nd and higher orders. "Should be in the hands of all in research in applied mathematics, teaching," NATURE. 21 figures. viii + 238pp. 5⅜ x 8. **S168 Paperbound $1.75**

NUMERICAL INTEGRATION OF DIFFERENTIAL EQUATIONS, Bennett, Milne & Bateman. Unabridged republication of original monograph prepared for National Research Council. New methods of integration of differential equations developed by 3 leading mathematicians: THE INTERPOLATIONAL POLYNOMIAL and SUCCESSIVE APPROXIMATIONS by A. A. Bennett; STEP-BY-STEP METHODS OF INTEGRATION by W. W. Milne, METHODS FOR PARTIAL DIFFERENTIAL EQUATIONS by H. Bateman. Methods for partial differential equations, transition from difference equations to differential equations, solution of differential equations to non-integral values of a parameter will interest mathematicians and physicists. 288 footnotes, mostly bibliographic; 235-item classified bibliography. 108pp. 5⅜ x 8. **S305 Paperbound $1.35**

INTRODUCTION TO RELAXATION METHODS, F. S. Shaw. Fluid mechanics, design of electrical networks, forces in structural frameworks, stress distribution, buckling, etc. Solve linear simultaneous equations, linear ordinary differential equations, partial differential equations, Eigen-value problems by relaxation methods. Detailed examples throughout. Special tables for dealing with awkwardly-shaped boundaries. Indexes. 253 diagrams. 72 tables. 400pp. 5⅜ x 8. **S244 Paperbound $2.45**

TABLES OF INDEFINITE INTEGRALS, G. Petit Bois. Comprehensive and accurate, this orderly grouping of over 2500 of the most useful indefinite integrals will save you hours of laborious mathematical groundwork. After a list of 49 common transformations of integral expressions, with a wide variety of examples, the book takes up algebraic functions, irrational monomials, products and quotients of binomials, transcendental functions, natural logs, etc. You will rarely or never encounter an integral of an algebraic or transcendental function not included here; any more comprehensive set of tables costs at least $12 or $15. Index. 2544 integrals. xii + 154pp. 6⅛ x 9¼. **S225 Paperbound $1.65**

A TABLE OF THE INCOMPLETE ELLIPTIC INTEGRAL OF THE THIRD KIND, R. G. Selfridge, J. E. Maxfield. The first complete 6 place tables of values of the incomplete integral of the third kind, prepared under the auspices of the Research Department of the U.S. Naval Ordnance Test Station. Calculated on an IBM type 704 calculator and thoroughly verified by echo-checking and a check integral at the completion of each value of a. Of inestimable value in problems where the surface area of geometrical bodies can only be expressed in terms of the incomplete integral of the third and lower kinds; problems in aero-, fluid-, and thermodynamics involving processes where nonsymmetrical repetitive volumes must be determined; various types of seismological problems; problems of magnetic potentials due to circular current; etc. Foreword. Acknowledgment. Introduction. Use of table. xiv + 805pp. 5⅝ x 8⅜. **S501 Clothbound $7.50**

MATHEMATICAL TABLES, H. B. Dwight. Unique for its coverage in one volume of almost every function of importance in applied mathematics, engineering, and the physical sciences. Three extremely fine tables of the three trig functions and their inverse functions to thousandths of radians, natural and common logarithms; squares, cubes; hyperbolic functions and the inverse hyperbolic functions, $(a^2 + b^2)$ exp. ½a; complete elliptic integrals of the 1st and 2nd kind; sine and cosine integrals; exponential integrals $Ei(x)$ and $Ei(-x)$; binomial coefficients; factorials to 250; surface zonal harmonics and first derivatives; Bernoulli and Euler numbers and their logs to base of 10; Gamma function; normal probability integral; over 60 pages of Bessel functions, the Riemann Zeta function. Each table with formulae generally used, sources of more extensive tables, interpolation data, etc. Over half have columns of differences, to facilitate interpolation. Introduction. Index. viii + 231pp. 5⅜ x 8.
S445 Paperbound $1.75

TABLES OF FUNCTIONS WITH FORMULAE AND CURVES, E. Jahnke & F. Emde. The world's most comprehensive 1-volume English-text collection of tables, formulae, curves of transcendent functions. 4th corrected edition, new 76-page section giving tables, formulae for elementary functions—not in other English editions. Partial contents: sine, cosine, logarithmic integral; factorial function; error integral; theta functions; elliptic integrals, functions; Legendre, Bessel, Riemann, Mathieu, hypergeometric functions, etc. Supplementary books. Bibliography. Indexed. "Out of the way functions for which we know no other source," SCIENTIFIC COMPUTING SERVICE, Ltd. 212 figures. 400pp. 5⅜ x 8. **S133 Paperbound $2.00**

JACOBIAN ELLIPTIC FUNCTION TABLES, L. M. Milne-Thomson. An easy to follow, practical book which gives not only useful numerical tables, but also a complete elementary sketch of the application of elliptic functions. It covers Jacobian elliptic functions and a description of their principal properties; complete elliptic integrals, Fourier series and power series expansions; periods, zeros, poles, residues, formulas for special values of the argument; transformations, approximations, elliptic integrals, conformal mapping, factorization of cubic and quartic polynomials; application to the pendulum problem; etc. Tables and graphs form the body of the book: Graph, 5 figure table of the elliptic function sn (u m); cn (u m); dn (u m). 8-figure table of complete elliptic integrals K, K', E, E', and the nome q. 7 figure table of the Jacobian zeta-function Z(u). 3 figures. xi + 123pp. 5⅜ x 8. **S194 Paperbound $1.35**

PHYSICS

General physics

FOUNDATIONS OF PHYSICS, R. B. Lindsay & H. Margenau. Excellent bridge between semi-popular works & technical treatises. A discussion of methods of physical description, construction of theory; valuable for physicist with elementary calculus who is interested in ideas that give meaning to data, tools of modern physics. Contents include symbolism, mathematical equations; space & time foundations of mechanics; probability; physics & continua; electron theory; special & general relativity; quantum mechanics; causality. "Thorough and yet not overdetailed. Unreservedly recommended," NATURE (London). Unabridged, corrected edition. List of recommended readings. 35 illustrations. xi + 537pp. 5⅜ x 8. **S377 Paperbound $2.45**

FUNDAMENTAL FORMULAS OF PHYSICS, ed. by D. H. Menzel. Highly useful, fully inexpensive reference and study text, ranging from simple to highly sophisticated operations. Mathematics integrated into text—each chapter stands as short textbook of field represented. Vol. 1: Statistics, Physical Constants, Special Theory of Relativity, Hydrodynamics, Aerodynamics, Boundary Value Problems in Math. Physics; Viscosity, Electromagnetic Theory, etc. Vol. 2: Sound, Acoustics, Geometrical Optics, Electron Optics, High-Energy Phenomena, Magnetism, Biophysics, much more. Index. Total of 800pp. 5⅜ x 8. **Vol. 1 S595 Paperbound $2.00**
Vol. 2 S596 Paperbound $2.00

MATHEMATICAL PHYSICS, D. H. Menzel. Thorough one-volume treatment of the mathematical techniques vital for classic mechanics, electromagnetic theory, quantum theory, and relativity. Written by the Harvard Professor of Astrophysics for junior, senior, and graduate courses, it gives clear explanations of all those aspects of function theory, vectors, matrices, dyadics, tensors, partial differential equations, etc., necessary for the understanding of the various physical theories. Electron theory, relativity, and other topics seldom presented appear here in considerable detail. Scores of definitions, conversion factors, dimensional constants, etc. "More detailed than normal for an advanced text . . excellent set of sections on Dyadics, Matrices, and Tensors," JOURNAL OF THE FRANKLIN INSTITUTE. Index. 193 problems, with answers. x + 412pp. 5⅜ x 8. **S56 Paperbound $2.00**

THE SCIENTIFIC PAPERS OF J. WILLARD GIBBS. All the published papers of America's outstanding theoretical scientist (except for "Statistical Mechanics" and "Vector Analysis"). Vol I (thermodynamics) contains one of the most brilliant of all 19th-century scientific papers—the 300-page "On the Equilibrium of Heterogeneous Substances," which founded the science of physical chemistry, and clearly stated a number of highly important natural laws for the first time; 8 other papers complete the first volume. Vol II includes 2 papers on dynamics, 8 on vector analysis and multiple algebra, 5 on the electromagnetic theory of light, and 6 miscellaneous papers. Biographical sketch by H. A. Bumstead. Total of xxxvi + 718pp. 5⅝ x 8⅜. **S721 Vol I Paperbound $2.00**
S722 Vol II Paperbound $2.00
The set $4.00

Relativity, quantum theory, nuclear physics

THE PRINCIPLE OF RELATIVITY, A. Einstein, H. Lorentz, M. Minkowski, H. Weyl. These are the 11 basic papers that founded the general and special theories of relativity, all translated into English. Two papers by Lorentz on the Michelson experiment, electromagnetic phenomena. Minkowski's SPACE & TIME, and Weyl's GRAVITATION & ELECTRICITY. 7 epochmaking papers by Einstein: ELECTROMAGNETICS OF MOVING BODIES, INFLUENCE OF GRAVITATION IN PROPAGATION OF LIGHT, COSMOLOGICAL CONSIDERATIONS, GENERAL THEORY, and 3 others. 7 diagrams. Special notes by A. Sommerfeld. 224pp. 5⅜ x 8.
S81 Paperbound **$1.75**

SPACE TIME MATTER, Hermann Weyl. "The standard treatise on the general theory of relativity," (Nature), written by a world-renowned scientist, provides a deep clear discussion of the logical coherence of the general theory, with introduction to all the mathematical tools needed: Maxwell, analytical geometry, non-Euclidean geometry, tensor calculus, etc. Basis is classical space-time, before absorption of relativity. Partial contents: Euclidean space, mathematical form, metrical continuum, relativity of time and space, general theory. 15 diagrams. Bibliography. New preface for this edition. xviii + 330pp. 5⅜ x 8. •
S267 Paperbound **$1.85**

PRINCIPLES OF QUANTUM MECHANICS, W. V. Houston. Enables student with working knowledge of elementary mathematical physics to develop facility in use of quantum mechanics, understand published work in field. Formulates quantum mechanics in terms of Schroedinger's wave mechanics. Studies evidence for quantum theory, for inadequacy of classical mechanics, 2 postulates of quantum mechanics, numerous important, fruitful applications of quantum mechanics in spectroscopy, collision problems, electrons in solids; other topics. "One of the most rewarding features . . . is the interlacing of problems with text," Amer. J. of Physics. Corrected edition. 21 illus. Index 296pp. 5⅜ x 8. S524 Paperbound **$1.85**

PHYSICAL PRINCIPLES OF THE QUANTUM THEORY, Werner Heisenberg. A Nobel laureate discusses quantum theory; Heisenberg's own work, Compton, Schroedinger, Wilson, Einstein, many others. Written for physicists, chemists who are not specialists in quantum theory, only elementary formulae are considered in the text; there is a mathematical appendix for specialists. Profound without sacrifice of clarity. Translated by C. Eckart, F. Hoyt. 18 figures. 192pp. 5⅜ x 8. S113 Paperbound **$1.25**

SELECTED PAPERS ON QUANTUM ELECTRODYNAMICS, edited by J. Schwinger. Facsimiles of papers which established quantum electrodynamics, from initial successes through today's position as part of the larger theory of elementary particles. First book publication in any language of these collected papers of Bethe, Bloch, Dirac, Dyson, Fermi, Feynman, Heisenberg, Kusch, Lamb, Oppenheimer, Pauli, Schwinger, Tomonoga, Weisskopf, Wigner, etc. 34 papers in all, 29 in English, 1 in French, 3 in German, 1 in Italian. Preface and historical commentary by the editor. xvii + 423pp. 6⅛ x 9¼. S444 Paperbound **$2.45**

THE FUNDAMENTAL PRINCIPLES OF QUANTUM MECHANICS, WITH ELEMENTARY APPLICATIONS, E. C. Kemble. An inductive presentation, for the graduate student or specialist in some other branch of physics. Assumes some acquaintance with advanced math; apparatus necessary beyond differential equations and advanced calculus is developed as needed. Although a general exposition of principles, hundreds of individual problems are fully treated, with applications of theory being interwoven with development of the mathematical structure. The author is the Professor of Physics at Harvard Univ. "This excellent book would be of great value to every student . . . a rigorous and detailed mathematical discussion of all of the principal quantum-mechanical methods . . . has succeeded in keeping his presentations clear and understandable," Dr. Linus Pauling, J. of the American Chemical Society. Appendices: calculus of variations, math. notes, etc. Indexes. 611pp. 5⅜ x 8.
S472 Paperbound **$2.95**

ATOMIC SPECTRA AND ATOMIC STRUCTURE, G. Herzberg. Excellent general survey for chemists, physicists specializing in other fields. Partial contents: simplest line spectra and elements of atomic theory, building-up principle and periodic system of elements, hyperfine structure of spectral lines, some experiments and applications. Bibliography. 80 figures. Index. xii + 257pp. 5⅜ x 8. S115 Paperbound **$1.95**

THE THEORY AND THE PROPERTIES OF METALS AND ALLOYS, N. F. Mott, H. Jones. Quantum methods used to develop mathematical models which show interrelationship of basic chemical phenomena with crystal structure, magnetic susceptibility, electrical, optical properties. Examines thermal properties of crystal lattice, electron motion in applied field, cohesion, electrical resistance, noble metals, para-, dia-, and ferromagnetism, etc. "Exposition . . . clear . . . mathematical treatment . . . simple," Nature. 138 figures. Bibliography. Index. xiii + 320pp. 5⅜ x 8. S456 Paperbound **$1.85**

FOUNDATIONS OF NUCLEAR PHYSICS, edited by R. T. Beyer. 13 of the most important papers on nuclear physics reproduced in facsimile in the original languages of their authors: the papers most often cited in footnotes, bibliographies. Anderson, Curie Joliot, Chadwick, Fermi, Lawrence, Cockcroft, Hahn, Yukawa. UNPARALLELED BIBLIOGRAPHY. 122 doublecolumned pages, over 4,000 articles, books classified. 57 figures. 288pp. 6⅛ x 9¼.
S19 Paperbound **$1.75**

MESON PHYSICS, R. E. Marshak. Traces the basic theory, and explicity presents results of experiments with particular emphasis on theoretical significance. Phenomena involving mesons as virtual transitions are avoided, eliminating some of the least satisfactory predictions of meson theory. Includes production and study of π mesons at nonrelativistic nucleon energies, contrasts between π and μ mesons, phenomena associated with nuclear interaction of π mesons, etc. Presents early evidence for new classes of particles and indicates theoretical difficulties created by discovery of heavy mesons and hyperons. Name and subject indices. Unabridged reprint. viii + 378pp. 5⅜ x 8.   S500 Paperbound **$1.95**

Hydrodynamics

HYDRODYNAMICS, H. Dryden, F. Murnaghan, Harry Bateman. Published by the National Research Council in 1932 this enormous volume offers a complete coverage of classical hydrodynamics. Encyclopedic in quality Partial contents physics of fluids, motion, turbulent flow, compressible fluids, motion in 1, 2, 3 dimensions; viscous fluids rotating, laminar motion, resistance of motion through viscous fluid, eddy viscosity, hydraulic flow in channels of various shapes, discharge of gases, flow past obstacles, etc. Bibliography of over 2,900 items. Indexes. 23 figures. 634pp. 5⅜ x 8.   S303 Paperbound **$2.75**

A TREATISE ON HYDRODYNAMICS, A. B. Basset. Favorite text on hydrodynamics for 2 generations of physicists, hydrodynamical engineers, oceanographers, ship designers, etc. Clear enough for the beginning student, and thorough source for graduate students and engineers on the work of d'Alembert, Euler, Laplace, Lagrange, Poisson, Green, Clebsch, Stokes, Cauchy, Helmholtz, J. J. Thomson, Love, Hicks, Greenhill, Besant, Lamb, etc. Great amount of documentation on entire theory of classical hydrodynamics. Vol I: theory of motion of frictionless liquids, vortex, and cyclic irrotational motion, etc. 132 exercises Bibliography. 3 Appendixes. xii + 264pp Vol II. motion in viscous liquids, harmonic analysis, theory of tides, etc. 112 exercises. Bibliography 4 Appendixes. xv + 328pp. Two volume set 5⅛ x 8
S724 Vol I Paperbound **$1.75**
S725 Vol II Paperbound **$1.75**
The set **$3.50**

HYDRODYNAMICS, Horace Lamb. Internationally famous complete coverage of standard reference work on dynamics of liquids & gases. Fundamental theorems, equations, methods, solutions, background, for classical hydrodynamics. Chapters include Equations of Motion, Integration of Equations in Special Gases, Irrotational Motion, Motion of Liquid in 2 Dimensions, Motion of Solids through Liquid-Dynamical Theory, Vortex Motion, Tidal Waves, Surface Waves, Waves of Expansion, Viscosity, Rotating Masses of liquids Excellently planned, arranged; clear, lucid presentation 6th enlarged, revised edition. Index. Over 900 footnotes, mostly bibliographical. 119 figures. xv + 738pp. 6⅛ x 9¼.   S256 Paperbound **$2.95**

See also: **FUNDAMENTAL FORMULAS OF PHYSICS, D. H. Menzel; THEORY OF FLIGHT, R. von Mises; FUNDAMENTALS OF HYDRO- AND AEROMECHANICS, L. Prandtl and O. G. Tietjens; APPLIED HYDRO- AND AEROMECHANICS, L. Prandtl and O. G. Tietjens; HYDRAULICS AND ITS APPLICATIONS, A. H. Gibson; FLUID MECHANICS FOR HYDRAULIC ENGINEERS, H. Rouse.**

Acoustics, optics, electromagnetics

ON THE SENSATIONS OF TONE, Hermann Helmholtz. This is an unmatched coordination of such fields as acoustical physics, physiology, experiment, history of music. It covers the entire gamut of musical tone Partial contents: relation of musical science to acoustics, physical vs. physiological acoustics, composition of vibration, resonance, analysis of tones by sympathetic resonance, beats, chords, tonality, consonant chords, discords, progression of parts, etc 33 appendices discuss various aspects of sound, physics, acoustics, music, etc. Translated by A. J. Ellis. New introduction by Prof. Henry Margenau of Yale. 68 figures. 43 musical passages analyzed. Over 100 tables. Index. xix + 576pp. 6⅛ x 9¼.
S114 Paperbound **$2.95**

THE THEORY OF SOUND, Lord Rayleigh. Most vibrating systems likely to be encountered in practice can be tackled successfully by the methods set forth by the great Nobel laureate, Lord Rayleigh. Complete coverage of experimental, mathematical aspects of sound theory. Partial contents: Harmonic motions, vibrating systems in general, lateral vibrations of bars, curved plates or shells, applications of Laplace's functions to acoustical problems, fluid friction, plane vortex-sheet, vibrations of solid bodies, etc. This is the first inexpensive edition of this great reference and study work. Bibliography. Historical introduction by R. B. Lindsay. Total of 1040pp. 97 figures. 5⅜ x 8.
S292, S293, Two volume set, paperbound, **$4.00**

THE DYNAMICAL THEORY OF SOUND, H. Lamb. Comprehensive mathematical treatment of the physical aspects of sound, covering the theory of vibrations, the general theory of sound, and the equations of motion of strings, bars, membranes, pipes, and resonators. Includes chapters on plane, spherical, and simple harmonic waves, and the Helmholtz Theory of Audition. Complete and self-contained development for student and specialist; all fundamental differential equations solved completely. Specific mathematical details for such important phenomena as harmonics, normal modes, forced vibrations of strings, theory of reed pipes, etc. Index. Bibliography. 86 diagrams. viii + 307pp. 5⅜ x 8.
S655 Paperbound **$1.50**

WAVE PROPAGATION IN PERIODIC STRUCTURES, L. Brillouin. A general method and application to different problems: pure physics, such as scattering of X-rays of crystals, thermal vibration in crystal lattices, electronic motion in metals; and also problems of electrical engineering. Partial contents: elastic waves in 1-dimensional lattices of point masses. Propagation of waves along 1-dimensional lattices. Energy flow. 2 dimensional, 3 dimensional lattices. Mathieu's equation. Matrices and propagation of waves along an electric line. Continuous electric lines. 131 illustrations. Bibliography. Index. xii + 253pp. 5⅜ x 8.
S34 Paperbound **$1.85**

THEORY OF VIBRATIONS, N. W. McLachlan. Based on an exceptionally successful graduate course given at Brown University, this discusses linear systems having 1 degree of freedom, forced vibrations of simple linear systems, vibration of flexible strings, transverse vibrations of bars and tubes, transverse vibration of circular plate, sound waves of finite amplitude, etc. Index. 99 diagrams. 160pp. 5⅜ x 8.
S190 Paperbound **$1.35**

LOUD SPEAKERS: THEORY, PERFORMANCE, TESTING AND DESIGN, N. W. McLachlan. Most comprehensive coverage of theory, practice of loud speaker design, testing, classic reference, study manual in field. First 12 chapters deal with theory, for readers mainly concerned with math. aspects, last 7 chapters will interest reader concerned with testing, design. Partial contents: principles of sound propagation, fluid pressure on vibrators, theory of moving-coil principle, transients, driving mechanisms, response curves, design of horn type moving coil speakers, electrostatic speakers, much more. Appendix. Bibliography. Index. 165 illustrations, charts. 411pp. 5⅜ x 8.
S588 Paperbound **$2.25**

MICROWAVE TRANSMISSION, J. S. Slater. First text dealing exclusively with microwaves, brings together points of view of field, circuit theory, for graduate student in physics, electrical engineering, microwave technician. Offers valuable point of view not in most later studies. Uses Maxwell's equations to study electromagnetic field, important in this area. Partial contents: infinite line with distributed parameters, impedance of terminated line, plane waves, reflections, wave guides, coaxial line, composite transmission lines, impedance matching, etc. Introduction. Index. 76 illus. 319pp. 5⅜ x 8.
S564 Paperbound **$1.50**

THE ANALYSIS OF SENSATIONS, Ernst Mach. Great study of physiology, psychology of perception, shows Mach's ability to see material freshly, his "incorruptible skepticism and independence." (Einstein) Relation of problems of psychological perception to classical physics, supposed dualism of physical and mental, principle of continuity, evolution of senses, will as organic manifestation, scores of experiments, observations in optics, acoustics, music, graphics, etc. New introduction by T. S. Szasz, M. D. 58 illus. 300-item bibliography. Index. 404pp 5⅜ x 8.
S525 Paperbound **$1.75**

APPLIED OPTICS AND OPTICAL DESIGN, A. E. Conrady. With publication of vol. 2, standard work for designers in optics is now complete for first time. Only work of its kind in English; only detailed work for practical designer and self-taught. Requires, for bulk of work, no math above trig Step-by-step exposition, from fundamental concepts of geometrical, physical optics, to systematic study, design, of almost all types of optical systems. Vol. 1: all ordinary ray-tracing methods; primary aberrations; necessary higher aberration for design of telescopes, low-power microscopes, photographic equipment. Vol. 2: (Completed from author's notes by R. Kingslake, Dir. Optical Design. Eastman Kodak.) Special attention to high-power microscope, anastigmatic photographic objectives. "An indispensable work," J., Optical Soc. of Amer. "As a practical guide this book has no rival," Transactions, Optical Soc. Index. Bibliography. 193 diagrams. 852pp. 6⅛ x 9¼.
Vol. 1 T611 Paperbound **$2.95**
Vol. 2 T612 Paperbound **$2.95**

THE THEORY OF OPTICS, Paul Drude. One of finest fundamental texts in physical optics, classic offers thorough coverage, complete mathematical treatment of basic ideas. Includes fullest treatment of application of thermodynamics to optics; sine law in formation of images, transparent crystals, magnetically active substances, velocity of light, apertures, effects depending upon them, polarization, optical instruments, etc. Introduction by A. A. Michelson. Index. 110 illus. 567pp. 5⅛ x 8.
S532 Paperbound **$2.45**

OPTICKS, Sir Isaac Newton. In its discussions of light, reflection, color, refraction, theories of wave and corpuscular theories of light, this work is packed with scores of insights and discoveries. In its precise and practical discussion of construction of optical apparatus, contemporary understandings of phenomena it is truly fascinating to modern physicists, astronomers, mathematicians. Foreword by Albert Einstein. Preface by I. B. Cohen of Harvard University. 7 pages of portraits, facsimile pages, letters, etc. cxvi + 414pp. 5⅜ x 8.
S205 Paperbound **$2.00**

OPTICS AND OPTICAL INSTRUMENTS: AN INTRODUCTION WITH SPECIAL REFERENCE TO PRACTICAL APPLICATIONS, B. K. Johnson. An invaluable guide to basic practical applications of optical principles, which shows how to set up inexpensive working models of each of the four main types of optical instruments—telescopes, microscopes, photographic lenses, optical projecting systems. Explains in detail the most important experiments for determining their accuracy, resolving power, angular field of view, amounts of aberration, all other necessary facts about the instruments. Formerly "Practical Optics." Index. 234 diagrams. Appendix. 224pp. 5⅜ x 8.
S642 Paperbound **$1.65**

PRINCIPLES OF PHYSICAL OPTICS, Ernst Mach. This classical examination of the propagation of light, color, polarization, etc. offers an historical and philosophical treatment that has never been surpassed for breadth and easy readability. Contents: Rectilinear propagation of light. Reflection, refraction. Early knowledge of vision. Dioptrics. Composition of light. Theory of color and dispersion. Periodicity. Theory of interference. Polarization. Mathematical representation of properties of light. Propagation of waves, etc. 279 illustrations, 10 portraits. Appendix. Indexes. 324pp. 5⅜ x 8.
S178 Paperbound **$1.75**

FUNDAMENTALS OF ELECTRICITY AND MAGNETISM, L. B. Loeb. For students of physics, chemistry, or engineering who want an introduction to electricity and magnetism on a higher level and in more detail than general elementary physics texts provide. Only elementary differential and integral calculus is assumed. Physical laws developed logically, from magnetism to electric currents, Ohm's law, electrolysis, and on to static electricity, induction, etc. Covers an unusual amount of material; one third of book on modern material: solution of wave equation, photoelectric and thermionic effects, etc. Complete statement of the various electrical systems of units and interrelations. 2 Indexes. 75 pages of problems with answers stated. Over 300 figures and diagrams. xix +669pp. 5⅜ x 8.
S745 Paperbound **$2.75**

THE ELECTROMAGNETIC FIELD, Max Mason & Warren Weaver. Used constantly by graduate engineers. Vector methods exclusively· detailed treatment of electrostatics, expansion methods, with tables converting any quantity into absolute electromagnetic, absolute electrostatic, practical units. Discrete charges, ponderable bodies, Maxwell field equations, etc. Introduction. Indexes. 416pp. 5⅜ x 8.
S185 Paperbound **$2.00**

ELECTRICAL THEORY ON THE GIORGI SYSTEM, P. Cornelius. A new clarification of the fundamental concepts of electricity and magnetism, advocating the convenient m k.s. system of units that is steadily gaining followers in the sciences. Illustrating the use and effectiveness of his terminology with numerous applications to concrete technical problems, the author here expounds the famous Giorgi system of electrical physics. His lucid presentation and well-reasoned, cogent argument for the universal adoption of this system form one of the finest pieces of scientific exposition in recent years. 28 figures. Index. Conversion tables for translating earlier data into modern units. Translated from 3rd Dutch edition by L. J. Jolley. x + 187pp. 5½ x 8¾.
S909 Clothbound **$6.00**

THEORY OF ELECTRONS AND ITS APPLICATION TO THE PHENOMENA OF LIGHT AND RADIANT HEAT, H. Lorentz. Lectures delivered at Columbia University by Nobel laureate Lorentz. Unabridged, they form a historical coverage of the theory of free electrons, motion, absorption of heat, Zeeman effect, propagation of light in molecular bodies, inverse Zeeman effect, optical phenomena in moving bodies, etc. 109 pages of notes explain the more advanced sections. Index. 9 figures. 352pp. 5⅜ x 8.
S173 Paperbound **$1.85**

TREATISE ON ELECTRICITY AND MAGNETISM, James Clerk Maxwell. For more than 80 years a seemingly inexhaustible source of leads for physicists, mathematicians, engineers. Total of 1082pp on such topics as Measurement of Quantities, Electrostatics, Elementary Mathematical Theory of Electricity, Electrical Work and Energy in a System of Conductors, General Theorems, Theory of Electrical Images, Electrolysis, Conduction, Polarization, Dielectrics, Resistance, etc. "The greatest mathematical physicist since Newton," Sir James Jeans. 3rd edition. 107 figures, 21 plates. 1082pp. 5⅜ x 8   S636-7, 2 volume set, paperbound **$4.00**

See also: **FUNDAMENTAL FORMULAS OF PHYSICS, D. H. Menzel; MATHEMATICAL ANALYSIS OF ELECTRICAL & OPTICAL WAVE MOTION, H. Bateman.**

Mechanics, dynamics, thermodynamics, elasticity

MECHANICS VIA THE CALCULUS, P. W. Norris, W. S. Legge. Covers almost everything, from linear motion to vector analysis: equations determining motion, linear methods, compounding of simple harmonic motions, Newton's laws of motion, Hooke's law, the simple pendulum, motion of a particle in 1 plane, centers of gravity, virtual work, friction, kinetic energy of rotating bodies, equilibrium of strings, hydrostatics, sheering stresses, elasticity, etc. 550 problems. 3rd revised edition. xii + 367pp. 6 x 9.
S207 Clothbound **$3.95**

MECHANICS, J. P. Den Hartog. Already a classic among introductory texts, the M.I.T. professor's lively and discursive presentation is equally valuable as a beginner's text, an engineering student's refresher, or a practicing engineer's reference. Emphasis in this highly readable text is on illuminating fundamental principles and showing how they are embodied in a great number of real engineering and design problems: trusses, loaded cables, beams, jacks, hoists, etc. Provides advanced material on relative motion and gyroscopes not usual in introductory texts. "Very thoroughly recommended to all those anxious to improve their real understanding of the principles of mechanics." MECHANICAL WORLD. Index. List of equations. 334 problems, all with answers. Over 550 diagrams and drawings. ix + 462pp. 5⅜ x 8.
S754 Paperbound **$2.00**

THEORETICAL MECHANICS: AN INTRODUCTION TO MATHEMATICAL PHYSICS, J. S. Ames, F. D. Murnaghan. A mathematically rigorous development of theoretical mechanics for the advanced student, with constant practical applications. Used in hundreds of advanced courses. An unusually thorough coverage of gyroscopic and baryscopic material, detailed analyses of the Corilis acceleration, applications of Lagrange's equations, motion of the double pendulum, Hamilton-Jacobi partial differential equations, group velocity and dispersion, etc. Special relativity is also included. 159 problems. 44 figures. ix + 462pp. 5⅜ x 8.
S461 Paperbound **$2.00**

THEORETICAL MECHANICS: STATICS AND THE DYNAMICS OF A PARTICLE, W. D. MacMillan. Used for over 3 decades as a self-contained and extremely comprehensive advanced undergraduate text in mathematical physics, physics, astronomy, and deeper foundations of engineering. Early sections require only a knowledge of geometry; later, a working knowledge of calculus. Hundreds of basic problems, including projectiles to the moon, escape velocity, harmonic motion, ballistics, falling bodies, transmission of power, stress and strain, elasticity, astronomical problems. 340 practice problems plus many fully worked out examples make it possible to test and extend principles developed in the text. 200 figures. xvii + 430pp. 5⅜ x 8.
S467 Paperbound **$2.00**

THEORETICAL MECHANICS: THE THEORY OF THE POTENTIAL, W. D. MacMillan. A comprehensive, well balanced presentation of potential theory, serving both as an introduction and a reference work with regard to specific problems, for physicists and mathematicians. No prior knowledge of integral relations is assumed, and all mathematical material is developed as it becomes necessary. Includes: Attraction of Finite Bodies, Newtonian Potential Function; Vector Fields, Green and Gauss Theorems; Attractions of Surfaces and Lines; Surface Distribution of Matter; Two-Layer Surfaces; Spherical Harmonics; Ellipsoidal Harmonics; etc. "The great number of particular cases . . . should make the book valuable to geophysicists and others actively engaged in practical applications of the potential theory," Review of Scientific Instruments. Index. Bibliography. xiii + 469pp 5⅜ x 8.
S486 Paperbound **$2.25**

THEORETICAL MECHANICS: DYNAMICS OF RIGID BODIES, W. D. MacMillan. Theory of dynamics of a rigid body is developed, using both the geometrical and analytical methods of instruction. Begins with exposition of algebra of vectors, it goes through momentum principles, motion in space, use of differential equations and infinite series to solve more sophisticated dynamics problems. Partial contents. moments of inertia, systems of free particles, motion parallel to a fixed plane, rolling motion, method of periodic solutions, much more. 82 figs. 199 problems. Bibliography. Indexes. xii + 476pp. 5⅜ x 8.
S641 Paperbound **$2.00**

MATHEMATICAL FOUNDATIONS OF STATISTICAL MECHANICS, A. I. Khinchin. Offering a precise and rigorous formulation of problems, this book supplies a thorough and up-to-date exposition. It provides analytical tools needed to replace cumbersome concepts, and furnishes for the first time a logical step-by-step introduction to the subject. Partial contents: geometry & kinematics of the phase space, ergodic problem, reduction to theory of probability, application of central limit problem, ideal monatomic gas, foundation of thermo-dynamics, dispersion and distribution of sum functions. Key to notations. Index. viii + 179pp. 5⅜ x 8.
S147 Paperbound **$1.35**

ELEMENTARY PRINCIPLES IN STATISTICAL MECHANICS, J. W. Gibbs. Last work of the great Yale mathematical physicist, still one of the most fundamental treatments available for advanced students and workers in the field. Covers the basic principle of conservation of probability of phase, theory of errors in the calculated phases of a system, the contributions of Clausius, Maxwell, Boltzmann, and Gibbs himself, and much more. Includes valuable comparison of statistical mechanics with thermodynamics: Carnot's cycle, mechanical definitions of entropy, etc. xvi + 208pp. 5⅜ x 8.
S707 Paperbound **$1.45**

THE DYNAMICS OF PARTICLES AND OF RIGID, ELASTIC, AND FLUID BODIES; BEING LECTURES ON MATHEMATICAL PHYSICS, A. G. Webster. The reissuing of this classic fills the need for a comprehensive work on dynamics. A wide range of topics is covered in unusually great depth, applying ordinary and partial differential equations. Part I considers laws of motion and methods applicable to systems of all sorts; oscillation, resonance, cyclic systems, etc. Part 2 is a detailed study of the dynamics of rigid bodies. Part 3 introduces the theory of potential; stress and strain, Newtonian potential functions, gyrostatics, wave and vortex motion, etc. Further contents: Kinematics of a point; Lagrange's equations; Hamilton's principle; Systems of vectors; Statics and dynamics of deformable bodies; much more, not easily found together in one volume. Unabridged reprinting of 2nd edition. 20 pages of notes on differential equations and the higher analysis. 203 illustrations. Selected bibliography. Index. xi + 588pp. 5⅜ x 8.
S522 Paperbound **$2.35**

WEIGHT-STRENGTH ANALYSIS OF AIRCRAFT STRUCTURES, F. R. Shanley. Scientifically sound methods of analyzing and predicting the structural weight of aircraft and missiles. Deals directly with forces and the distances over which they must be transmitted, making it possible to develop methods by which the minimum structural weight can be determined for any material and conditions of loading. Weight equations for wing and fuselage structures. Includes author's original papers on inelastic buckling and creep buckling. "Particularly successful in presenting his analytical methods for investigating various optimum design principles," AERONAUTICAL ENGINEERING REVIEW. Enlarged bibliography. Index. 199 figures. xiv + 404pp. 5⅝ x 8⅜. S660 Paperbound **$2.45**

INTRODUCTION TO THE STATISTICAL DYNAMICS OF AUTOMATIC CONTROL SYSTEMS, V. V. Solodovnikov. First English publication of text-reference covering important branch of automatic control systems—random signals; in its original edition, this was the first comprehensive treatment. Examines frequency characteristics, transfer functions, stationary random processes, determination of minimum mean-squared error, of transfer function for a finite period of observation, much more. Translation edited by J. B. Thomas, L. A. Zadeh. Index. Bibliography. Appendix. xxii + 308pp. 5⅜ x 8. S420 Paperbound **$2.25**

TENSORS FOR CIRCUITS, Gabriel Kron. A boldly original method of analysing engineering problems, at center of sharp discussion since first introduced, now definitely proved useful in such areas as electrical and structural networks on automatic computers. Encompasses a great variety of specific problems by means of a relatively few symbolic equations. "Power and flexibility . . . becoming more widely recognized," Nature. Formerly "A Short Course in Tensor Analysis." New introduction by B. Hoffmann. Index. Over 800 diagrams. xix + 250pp. 5⅜ x 8. S534 Paperbound **$1.85**

DESIGN AND USE OF INSTRUMENTS AND ACCURATE MECHANISM, T. N. Whitehead. For the instrument designer, engineer; how to combine necessary mathematical abstractions with independent observation of actual facts. Partial contents: instruments & their parts, theory of errors, systematic errors, probability, short period errors, erratic errors, design precision, kinematic, semikinematic design, stiffness, planning of an instrument, human factor, etc. Index. 85 photos, diagrams. xii + 288pp. 5⅜ x 8. S270 Paperbound **$1.95**

APPLIED ELASTICITY, J. Prescott. Provides the engineer with the theory of elasticity usually lacking in books on strength of materials, yet concentrates on those portions useful for immediate application. Develops every important type of elasticity problem from theoretical principles. Covers analysis of stress, relations between stress and strain, the empirical basis of elasticity, thin rods under tension or thrust, Saint Venant's theory, transverse oscillations of thin rods, stability of thin plates, cylinders with thin walls, vibrations of rotating disks, elastic bodies in contact, etc. "Excellent and important contribution to the subject, not merely in the old matter which he has presented in new and refreshing form, but also in the many original investigations here published for the first time," NATURE. Index. 3 Appendixes. vi + 672pp. 5⅜ x 8. S726 Paperbound **$2.95**

STRENGTH OF MATERIALS, J. P. Den Hartog. Distinguished text prepared for M.I.T. course, ideal as introduction, refresher, reference, or self-study text Full clear treatment of elementary material (tension, torsion, bending, compound stresses, deflection of beams, etc.), plus much advanced material on engineering methods of great practical value: full treatment of the Mohr circle, lucid elementary discussions of the theory of the center of shear and the "Myosotis" method of calculating beam deflections, reinforced concrete, plastic deformations, photoelasticity, etc. In all sections, both general principles and concrete applications are given. Index. 186 figures (160 others in problem section). 350 problems, all with answers. List of formulas. viii + 323pp. 5⅜ x 8. S755 Paperbound **$1.95**

PHOTOELASTICITY: PRINCIPLES AND METHODS, H. T. Jessop, F. C. Harris. For the engineer, for specific problems of stress analysis. Latest time-saving methods of checking calculations in 2-dimensional design problems, new techniques for stresses in 3 dimensions, and lucid description of optical systems used in practical photoelasticity. Useful suggestions and hints based on on-the-job experience included. Partial contents: strained and stress-strain relations, circular disc under thrust along diameter, rectangular block with square hole under vertical thrust, simply supported rectangular beam under central concentrated load, etc. Theory held to minimum, no advanced mathematical training needed. Index. 164 illustrations. viii + 184pp. 6⅛ x 9¼. S137 Clothbound **$3.75**

MECHANICS OF THE GYROSCOPE, THE DYNAMICS OF ROTATION, R. F. Deimel, Professor of Mechanical Engineering at Stevens Institute of Technology. Elementary general treatment of dynamics of rotation, with special application of gyroscopic phenomena. No knowledge of vectors needed. Velocity of a moving curve, acceleration to a point, general equations of motion, gyroscopic horizon, free gyro, motion of discs, the damped gyro, 103 similar topics. Exercises. 75 figures. 208pp. 5⅜ x 8. S66 Paperbound **$1.65**
S144 Paperbound **$1.98**

A TREATISE ON GYROSTATICS AND ROTATIONAL MOTION: THEORY AND APPLICATIONS, Andrew Gray. Most detailed, thorough book in English, generally considered definitive study. Many problems of all sorts in full detail, or step-by-step summary. Classical problems of Bour, Lottner, etc.; later ones of great physical interest. Vibrating systems of gyrostats, earth as a top, calculation of path of axis of a top by elliptic integrals, motion of unsymmetrical top, much more. Index. 160 illus. 550pp. 5⅜ x 8. S589 Paperbound **$2.75**

FUNDAMENTALS OF HYDRO- AND AEROMECHANICS, L. Prandtl and O. G. Tietjens. The well-known standard work based upon Prandtl's lectures at Goettingen. Wherever possible hydro-dynamics theory is referred to practical considerations in hydraulics, with the view of unifying theory and experience. Presentation is extremely clear and though primarily physical, mathematical proofs are rigorous and use vector analysis to a considerable extent. An Enginering Society Monograph, 1934. 186 figures. Index. xvi + 270pp. 5⅜ x 8.
                                                                        S374 Paperbound **$1.85**

APPLIED HYDRO- AND AEROMECHANICS, L. Prandtl and O. G. Tietjens. Presents, for the most part, methods which will be valuable to engineers. Covers flow in pipes, boundary layers, airfoil theory, entry conditions, turbulent flow in pipes, and the boundary layer, determining drag from measurements of pressure and velocity, etc. "Will be welcomed by all students of aerodynamics," NATURE. Unabridged, unaltered. An Engineering Society Monograph, 1934. Index. 226 figures, 28 photographic plates illustrating flow patterns. xvi + 311pp. 5⅜ x 8.
                                                                        S375 Paperbound **$1.85**

HYDRAULICS AND ITS APPLICATIONS, A. H. Gibson. Excellent comprehensive textbook for the student and thorough practical manual for the professional worker, a work of great stature in its area. Half the book is devoted to theory and half to applications and practical prob-lems met in the field. Covers modes of motion of a fluid, critical velocity, viscous flow, eddy formation, Bernoulli's theorem, flow in converging passages, vortex motion, form of effluent streams, notches and weirs, skin friction, losses at valves and elbows, siphons, erosion of channels, jet propulsion, waves of oscillation, and over 100 similar topics. Final chapters (nearly 400 pages) cover more than 100 kinds of hydraulic machinery: Pelton wheel, speed regulators, the hydraulic ram, surge tanks, the scoop wheel, the Venturi meter, etc. A special chapter treats methods of testing theoretical hypotheses: scale models of rivers, tidal estuaries, siphon spillways, etc. 5th revised and enlarged (1952) edition. Index. Ap-pendix. 427 photographs and diagrams. 95 examples, answers. xv + 813pp. 6 x 9.
                                                                        S791 Clothbound **$8.00**

FLUID MECHANICS FOR HYDRAULIC ENGINEERS, H. Rouse. Standard work that gives a coherent picture of fluid mechanics from the point of view of the hydraulic engineer. Based on courses given to civil and mechanical engineering students at Columbia and the California Institute of Technology, this work covers every basic principle, method, equation, or theory of interest to the hydraulic engineer. Much of the material, diagrams, charts, etc., in this self-contained text are not duplicated elsewhere. Covers irrotational motion, conformal map-ping, problems in laminar motion, fluid turbulence, flow around immersed bodies, transporta-tion of sediment, general charcteristics of wave phenomena, gravity waves in open channels, etc. Index. Appendix of physical properties of common fluids. Frontispiece + 245 figures and photographs. xvi + 422pp. 5⅜ x 8.   S729 Paperbound **$2.25**

THE MEASUREMENT OF POWER SPECTRA FROM THE POINT OF VIEW OF COMMUNICATIONS ENGINEERING, R. B. Blackman, J. W. Tukey. This pathfinding work, reprinted from the "Bell System Technical Journal," explains various ways of getting practically useful answers in the measurement of power spectra, using results from both transmission theory and the theory of statistical estimation. Treats: Autocovariance Functions and Power Spectra; Direct Analog Computation; Distortion, Noise, Heterodyne Filtering and Pre-whitening; Aliasing; Rejection Filtering and Separation; Smoothing and Decimation Procedures; Very Low Fre-quencies; Transversal Filtering; much more. An appendix reviews fundamental Fourier tech-niques. Index of notation. Glossary of terms. 24 figures. XII tables. Bibliography. General index. 192pp. 5⅜ x 8.   S507 Paperbound **$1.85**

MICROWAVE TRANSMISSION DESIGN DATA, T. Moreno. Originally classified, now rewritten and enlarged (14 new chapters) for public release under auspices of Sperry Corp. Material of immediate value or reference use to radio engineers, systems designers, applied physicists, etc. Ordinary transmission line theory; attenuation; capacity; parameters of coaxial lines; higher modes; flexible cables; obstacles, discontinuities, and :njunctions; tuneable wave guide impedance transformers; effects of temperature and humidity; much more. "Enough theoretical discussion is included to allow use of data without previous background," Electronics. 324 circuit diagrams, figures, etc. Tables of dielectrics, flexible cable, etc., data. Index. Ix + 248pp. 5⅜ x 8.   S459 Paperbound **$1.50**

GASEOUS CONDUCTORS: THEORY AND ENGINEERING APPLICATIONS, J. D. Cobine. An indis-pensable text and reference to gaseous conduction phenomena, with the engineering view-point prevailing throughout. Studies the kinetic theory of gases, ionization, emission phe-nomena; gas breakdown, spark characteristics, glow, and discharges; engineering applica-tions in circuit interrupters, rectifiers, light sources, etc. Separate detailed treatment of high pressure arcs (Suits); low pressure arcs (Langmuir and Tonks). Much more. "Well organized, clear, straightforward," Tonks, Review of Scientific Instruments. Index. Bibliog-raphy. 83 practice problems. 7 appendices. Over 600 figures. 58 tables. xx + 606pp. 5⅜ x 8.   S442 Paperbound **$2.85**

CHEMISTRY AND PHYSICAL CHEMISTRY

ORGANIC CHEMISTRY, F. C. Whitmore. The entire subject of organic chemistry for the practicing chemist and the advanced student Storehouse of facts, theories, processes found elsewhere only in specialized journals. Covers aliphatic compounds (500 pages on the properties and synthetic preparation of hydrocarbons, halides, proteins, ketones, etc), alicyclic compounds, aromatic compounds, heterocyclic compounds, organophosphorus and organometallic compounds. Methods of synthetic preparation analyzed critically throughout. Includes much of biochemical interest "The scope of this volume is astonishing," INDUSTRIAL AND ENGINEERING CHEMISTRY. 12,000-reference index 2387-item bibliography Total of x + 1005pp. 5⅜ x 8. Two volume set.
S700 Vol I Paperbound **$2.00**
S701 Vol II Paperbound **$2.00**
The set **$4.00**

THE PRINCIPLES OF ELECTROCHEMISTRY, D. A. McInnes. Basic equations for almost every subfield of electrochemistry from first principle referring at all times to the soundest and most recent theories and results, unusually useful as text or as reference. Covers coulometers and Faraday's Law, electrolytic conductance, the Debye-Hueckel method for the theoretical calculation of activity coefficients, concentration cells, standard electrode potentials, thermodynamic ionization constants, pH, potentiometric titrations, irreversible phenomena, Planck's equation, and much more. "Excellent treatise," AMERICAN CHEMICAL SOCIETY JOURNAL. "Highly recommended," CHEMICAL AND METALLURGICAL ENGINEERING 2 Indices. Appendix. 585-item bibliography. 137 figures. 94 tables ii + 478pp. 5⅝ x 8⅜
S52 Paperbound **$2.35**

THE CHEMISTRY OF URANIUM: THE ELEMENT, ITS BINARY AND RELATED COMPOUNDS, J. J. Katz and E. Rabinowitch. Vast post-World War II collection and correlation of thousands of AEC reports and published papers in a useful and easily accessible form, still the most complete and up-to-date compilation Treats "dry uranium chemistry," occurrences, preparation, properties, simple compounds, isotopic composition, extraction from ores, spectra, alloys, etc Much material available only here Index. Thousands of evaluated bibliographical references. 324 tables, charts, figures. xxi + 609pp 5⅜ x 8
S757 Paperbound **$2.95**

KINETIC THEORY OF LIQUIDS, J. Frenkel. Regarding the kinetic theory of liquids as a generalization and extension of the theory of solid bodies, this volume covers all types of arrangements of solids, thermal displacements of atoms, interstitial atoms and ions, orientational and rotational motion of molecules, and transition between states of matter. Mathematical theory is developed close to the physical subject matter 216 bibliographical footnotes. 55 figures. xi + 485pp. 5⅜ x 8
S94 Clothbound **$3.95**
S95 Paperbound **$2.45**

POLAR MOLECULES, Pieter Debye. This work by Nobel laureate Debye offers a complete guide to fundamental electrostatic field relations, polarizability, molecular structure Partial contents. electric intensity, displacement and force, polarization by orientation, molar polarization and molar refraction, halogen-hydrides, polar liquids, ionic saturation, dielectric constant, etc. Special chapter considers quantum theory Indexed 172pp 5⅛ x 8.
S64 Paperbound **$1.50**

ELASTICITY, PLASTICITY AND STRUCTURE OF MATTER, R. Houwink. Standard treatise on rheological aspects of different technically important solids such as crystals, resins, textiles, rubber, clay, many others. Investigates general laws for deformations; determines divergences from these laws for certain substances. Covers general physical and mathematical aspects of plasticity, elasticity, viscosity. Detailed examination of deformations, internal structure of matter in relation to elastic and plastic behavior, formation of solid matter from a fluid, conditions for elastic and plastic behavior of matter. Treats glass, asphalt, gutta percha, balata, proteins, baker's dough, lacquers, sulphur, others. 2nd revised, enlarged edition. Extensive revised bibliography in over 500 footnotes. Index. Table of symbols. 214 figures. xviii + 368pp. 6 x 9¼.
S385 Paperbound **$2.45**

THE PHASE RULE AND ITS APPLICATION, Alexander Findlay. Covering chemical phenomena of 1, 2, 3, 4, and multiple component systems, this "standard work on the subject" (NATURE, London), has been completely revised and brought up to date by A. N. Campbell and N. O. Smith. Brand new material has been added on such matters as binary, tertiary liquid equilibria, solid solutions in ternary systems, quinary systems of salts and water. Completely revised to triangular coordinates in ternary systems, clarified graphic representation, solid models, etc. 9th revised edition. Author, subject indexes. 236 figures. 505 footnotes, mostly bibliographic. xii + 494pp. 5⅜ x 8.
S91 Paperbound **$2.45**

TERNARY SYSTEMS: INTRODUCTION TO THE THEORY OF THREE COMPONENT SYSTEMS, G. Masing. Furnishes detailed discussion of representative types of 3-components systems, both in solid models (particularly metallic alloys) and isothermal models. Discusses mechanical mixture without compounds and without solid solutions; unbroken solid solution series; solid solutions with solubility breaks in two binary systems; iron-silicon-aluminum alloys; allotropic forms of iron in ternary system; other topics. Bibliography. Index. 166 illustrations. 178pp. 5⅝ x 8⅜. **S631 Paperbound $1.45**

THE STORY OF ALCHEMY AND EARLY CHEMISTRY, J. M. Stillman. An authoritative, scholarly work, highly readable, of development of chemical knowledge from 4000 B.C. to downfall of phlogiston theory in late 18th century. Every important figure, many quotations. Brings alive curious, almost incredible history of alchemical beliefs, practices, writings of Arabian Prince Oneeyade, Vincent of Beauvais, Geber, Zosimos, Paracelsus, Vitruvius, scores more. Studies work, thought of Black, Cavendish, Priestley, Van Helmont, Bergman, Lavoisier, Newton, etc. Index. Bibliography. 579pp. 5⅜ x 8. **S628 Paperbound $2.45**

See also: **ATOMIC SPECTRA AND ATOMIC STRUCTURE, G. Herzberg; INVESTIGATIONS ON THE THEORY OF THE BROWNIAN MOVEMENT, A. Einstein; TREATISE ON THERMODYNAMICS, M. Planck.**

ASTRONOMY AND ASTROPHYSICS

AN ELEMENTARY SURVEY OF CELESTIAL MECHANICS, Y. Ryabov. Elementary exposition of gravitational theory and celestial mechanics. Historical introduction and coverage of basic principles, including: the elliptic, the orbital plane, the 2- and 3 body problems, the discovery of Neptune, planetary rotation, the length of the day, the shapes of galaxies, satellites (detailed treatment of Sputnik I), etc. First American reprinting of successful Russian popular exposition. Elementary algebra and trigonometry helpful, but not necessary; presentation chiefly verbal. Appendix of theorem proofs. 58 figures. 165pp. 5⅜ x 8. **T756 Paperbound $1.25**

THE SKY AND ITS MYSTERIES, E. A. Beet. One of most lucid books on mysteries of universe; deals with astronomy from earliest observations to latest theories of expansion of universe, source of stellar energy, birth of planets, origin of moon craters, possibility of life on other planets. Discusses effects of sunspots on weather; distances, ages of several stars; master plan of universe; methods and tools of astronomers; much more. "Eminently readable book," London Times. Extensive bibliography. Over 50 diagrams. 12 full-page plates, fold-out star map. Introduction. Index, 238pp. 5¼ x 7½. **T627 Clothbound $3.00**

THE REALM OF THE NEBULAE, E. Hubble. One of the great astronomers of our time records his formulation of the concept of "island universes," and its impact on astronomy. Such topics are covered as the velocity-distance relation; classification, nature, distances, general field of nebulae; cosmological theories; nebulae in the neighborhood of the Milky Way. 39 photos of nebulae, nebulae clusters, spectra of nebulae, and velocity distance relations shown by spectrum comparison. "One of the most progressive lines of astronomical research," The Times (London). New introduction by A. Sandage. 55 illustrations. Index. iv + 201pp. 5⅜ x 8. **S455 Paperbound $1.50**

OUT OF THE SKY, H. H. Nininger. A non-technical but comprehensive introduction to "meteoritics", the young science concerned with all aspects of the arrival of matter from outer space. Written by one of the world's experts on meteorites, this work shows how, despite difficulties of observation and sparseness of data, a considerable body of knowledge has arisen. It defines meteors and meteorites; studies fireball clusters and processions, meteorite composition, size, distribution, showers, explosions, origins, craters, and much more. A true connecting link between astronomy and geology. More than 175 photos, 22 other illustrations. References. Bibliography of author's publications on meteorites. Index. viii + 336pp. 5⅜ x 8. **T519 Paperbound $1.85**

SATELLITES AND SCIENTIFIC RESEARCH, D. King-Hele. Non-technical account of the manmade satellites and the discoveries they have yielded up to the spring of 1959. Brings together information hitherto published only in hard-to-get scientific journals. Includes the life history of a typical satellite, methods of tracking, new information on the shape of the earth, zones of radiation, etc. Over 60 diagrams and 6 photographs. Mathematical appendix. Bibliography of over 100 items. Index. xii + 180pp. 5⅜ x 8½. **T703 Clothbound $4.00**

HOW TO MAKE A TELESCOPE, Jean Texereau. Enables the most inexperienced to choose, design, and build an f/6 or f/8 Newtonian type reflecting telescope, with an altazimuth Couder mounting, suitable for lunar, planetary, and stellar observation. A practical step-by-step course covering every operation and every piece of equipment. Basic principles of geometric and physical optics are discussed (though unnecessary to construction), and the merits of reflectors and refractors compared. A thorough discussion of eyepieces, finders, grinding, installation, testing, using the instrument, etc. 241 figures and 38 photos show almost every operation and tool. Potential errors are anticipated as much as possible. Foreword by A. Couder. Bibliography and sources of supply listing. Index. xiii + 191pp. 6¼ x 10. **T464 Clothbound $3.50**

Heat and Its

Morton Mott-Smith

Many of the facts in this book will probably con   . in
the study of physics. Do you know, for example,   le   ir below
32 degrees Fahrenheit without freezing? Do ve   il a J freeze
simultareously? Do you know why a swimmer   it is the same
temperature as the warm air above the water?

"Heat and Its Workings covers the theory and   the laws govern-
ing the effect of heat on solids, liquids, and   y which heat is
measured, the conversion of a substance from   through heating
and cooling; evaporation and its dependence   effects of pressure
on boiling and freezing points, and the th   that is transmitted
(conduction, convection, radiation). Brief   that led to major
discoveries in connection with heat len   to the discussion
of these subjects.

Since the topic of heat cannot be completely separated i   other aspects of physics,
the reader will learn a great deal about the properties of matter, the mo   ar
theory, transmission of light, conservation of energy, character..tics of m ist..
composition of the atmosphere, capillary action, thermal expansion, effect   co..
traction and expansion, elasticity, humidity, osmotic pressure and other related topics

This is one of the l   elementary introductions to the subject of heat ever writte.
Concise but complete, it presents virtually all the essential facts about heat in a
simple, readable style that makes them entirely comprehensible even to those who
have no previous knowledge of physics. Laymen will find that this book gives them
a first-rate background to this important topic in physics.

Unabridged, unaltered republication   original edition. Inde.. Pib.. grar y. 50 illus
trations. x + 165pp. 5⅜ x 8¼.   978 Paperbound $1.00

THIS DOVER EDITION IS DESIGNED F   ARS OF USE

THE PAPER is chemically the same quality as you wou   find in bo..'s priced $5.00 or
more. It does not discolor or become brittle with age. Not artificially bulked, either;
this edition is an unabridged full-length book, but is still easy to handle.

THE BINDING: The pages in this book are SEWN in signatures, in the method tradition-
ally used for the best books. These books open flat for easy reading and reference.
Pages do not drop out, the binding does not crack and split (as is the case with
many paperbooks held together with glue).

THE TYPE IS LEGIBLE: Margins are ample and allow for cloth rebinding.
